PROGRAM DESCRIPTION

The San Francisco Public Utilities Commission (SFPUC) proposes to adopt and implement the Water System Improvement Program (WSIP) to increase the reliability of the regional water system, which provides drinking water to 2.4 million people in San Francisco, San Mateo, Santa Clara, Alameda, and Tuolumne Counties. WSIP implementation would involve using additional water supplies to serve customer needs through 2030 as well as constructing repairs and improvements to many facilities within the existing system located in Tuolumne, Stanislaus, San Joaquin, Alameda, Santa Clara, San Mateo, and San Francisco Counties.

SUMMARY OF IMPACT ANALYSIS

The Draft PEIR evaluates the environmental effects of the proposed changes in water supply, including growth-inducing impacts, as well as the general environmental effects of implementing 22 facility projects. The analysis in the Draft PEIR finds that the WSIP would support planned growth in the existing SFPUC service area and indirect effects of growth are significant and unavoidable. All other impacts resulting from water supply changes could be mitigated to a less-than-significant level, with the exception of an unavoidable impact on streamflow for about two miles in Alameda Creek and a potentially significant and unavoidable fisheries impact in Crystal Springs Reservoir. Other potentially significant but mitigable impacts as a result of water supply changes include: impacts on water quality, fishery resources, terrestrial biological resources, recreation and visual resources in the watersheds of either the Tuolumne River, Alameda Creek, San Mateo Creek, or Pilarcitos Creek; and impacts on groundwater and related resources in the Westside Groundwater Basin.

The environmental analysis also determined that most of the impacts associated with implementing facility projects could be mitigated to a less-than-significant level, although some impacts in the areas of land use, visual resources, cultural resources, biological resources, noise, vibration, air quality, and traffic were conservatively identified as potentially significant and unavoidable at the programmatic level. These impact determinations may be revised during subsequent environmental review of individual facility improvement projects. The Draft PEIR identifies potentially significant, but mitigable impacts from construction and operation of 22 facility projects in the areas of land use, visual quality, geology, hydrology/water quality, biological resources, cultural resources, traffic, air quality, noise, vibration, public services, utilities, recreational resources, agricultural resources, hazards, and energy.

The Draft PEIR also evaluates the environmental effects of variations of and alternatives to the WSIP.

PUBLIC HEARINGS

The San Francisco Planning Department will hold five public hearings on this Draft PEIR at the locations listed below. The same information and opportunity to comment will be provided at each meeting. See the maps on the reverse side of this notice for directions to meeting locations.

Sonora	Modesto	Fremont	Palo Alto	San Francisco
September 5, 2007	September 6, 2007	September 18, 2007	September 19, 2007	September 20, 2007

**Call (415) 558-6422 the week of the hearing for a recorded message giving a more specific time.*

PUBLIC COMMENTS

Public comments on the Draft PEIR will be accepted by the San Francisco Planning Department from Friday, June 29, 2007 through 5:00 pm on Monday, October 1, 2007. You may submit comments to the Planning Department using any of the following means:

- Provide oral or written comment at any of the five public hearings
- Mail written comments to the San Francisco Planning Department, Attention: Paul Maltzer, Environmental Review Officer, WSIP PEIR, 1650 Mission Street, Suite 400, San Francisco, CA 94103
- E-mail written comments to: *wsip.peir.comments@gmail.com*

The San Francisco Planning Department will prepare written responses to comments received during the public review period in a Comments and Responses document. If you have any questions about the environmental review of the WSIP, please leave a message for the Planning Department at **1-866-231-1337**.

PUBLIC NOTICE

NO. 07-277

NOTICE OF HEARING ON DRAFT PROGRAM ENVIRONMENTAL IMPACT REPORT FOR THE FOLLOWING

2005.0159E- WATER SYSTEM IMPROVEMENT PROGRAM (WSIP). The San Francisco Public Utilities Commission (SFPUC) proposes to adopt and implement the WSIP to increase the reliability of the regional water system, which provides drinking water to 2.4 million people in San Francisco, San Mateo, Santa Clara, Alameda, and Tuolumne Counties. WSIP implementation would involve using additional water supplies to serve customer needs through 2030 as well as construction of repairs and/or improvements to many facilities within the existing system located in Tuolumne, Stanislaus, San Joaquin, Alameda, Santa Clara, San Mateo, and San Francisco Counties.

Notice is hereby given to the general public as follows:

1) A Draft Program Environmental Impact Report (PEIR) on the WSIP has been prepared by the San Francisco Planning Department to identify potentially significant environmental effects of the proposed program, ways to minimize those effects, and feasible alternatives. The report can be viewed online at www.sfgov.org/site/planning/mea (or by linking to this site from http://PEIR.sfwater.org). A printed copy of the report is available for public review and comment at the Planning Department offices at 1660 Mission Street, 1st Floor, Planning Information Counter. A printed copy of the report and associated reference materials are available for review by appointment at the San Francisco Public Utilities Commission by calling 1-866-231-1337 or e-mailing PEIRappointments@sfwater.org. They also can be viewed at:

- Alameda County/City of Fremont Library: 2400 Stevenson Boulevard, Fremont
- San Francisco Main Library: 100 Larkin Street San Francisco
- Stockton-San Joaquin County Public Library: 605 N. El Dorado St, Stockton
- San Mateo County/Belmont Library: 25 Tower Road, San Mateo
- San Jose-Dr. Martin Luther King, Jr. Library: 150 East San Fernando, San Jose
- Tuolumne County Library: 480 Greenley Road, Sonora

2) The Draft PEIR evaluates the environmental effects of the proposed changes in water supply, including growth-inducing impacts, as well as the general environmental effects of implementing 22 facility projects. The analysis in the Draft PEIR finds that the WSIP would support planned growth in the existing SFPUC service area and indirect effects of growth are significant and unavoidable. All other impacts resulting from water supply changes could be mitigated to a less-than-significant level, with the exception of an unavoidable impact on streamflow for about two miles in Alameda Creek and a potentially significant and unavoidable fisheries impact in Crystal Springs Reservoir. The environmental analysis also determined that most of the impacts associated with implementing facility projects could be mitigated to a less-than-significant level, although some impacts in the areas of land use, visual resources, cultural resources, biological resources, noise, vibration, air quality, and traffic were conservatively identified as potentially significant and unavoidable at the programmatic level. These impact determinations may be revised during subsequent environmental review of individual facility improvement projects.

3) Public hearings on this Draft PEIR have been scheduled as follows:

- Sept. 5 6:30 p.m.: Sonora Opera House, 250 S. Washington Street, Sonora
- Sept. 6 6:30 p.m.: Thomas Downey High School Cafeteria, 1000 Coffee Rd, Modesto
- Sept. 18 6:30 p.m.: Fremont Main Library, Fukaya Room, 2400 Stevenson Blvd, Fremont
- Sept. 19 6:30 p.m.: Avenidas Senior Center, 450 Bryant, Palo Alto
- Sept. 20 1:30 p.m. or later: San Francisco Planning Commission, City Hall, Rm 400, 1 Dr. Carlton B. Goodlett Place, San Francisco (Call 558-6422 the week of the hearing for a recorded message giving a more specific time).

4) Public comments on the Draft PEIR will be accepted by the San Francisco Planning Department from Friday, June 29 through 5: 00 p.m. on Monday, October 1, 2007. You may submit comments to the Planning Department using any of the following means: provide oral or written comments at a public hearing; mail comments to the San Francisco Planning Department, attention: Paul Maltzer, Environmental Review Officer, WSIP PEIR, 1650 Mission Street, Suite 400, San Francisco, CA 94103, or e-mail comments to wsip.peir.comments@gmail.com. The San Francisco Planning Department will prepare written responses to comments received during the public review period in a Comments and Responses document. If you have any questions about the environmental review of the WSIP, please leave a message for the Planning Department at 1-866-231-1337.

NOTICE OF HEARING ON DRAFT PROGRAM ENVIRONMENTAL IMPACT REPORT FOR THE FOLLOWING

2005.0159E- WATER SYSTEM IMPROVEMENT PROGRAM (WSIP). The San Francisco Public Utilities Commission (SFPUC) proposes to adopt and implement the WSIP to increase the reliability of the regional water system, which provides drinking water to 2.4 million people in San Francisco, San Mateo, Santa Clara, Alameda, and Tuolumne Counties. WSIP implementation would involve using additional water supplies to serve customer needs through 2030 as well as construction of repairs and/or improvements to many facilities within the existing system located in Tuolumne, Stanislaus, San Joaquin, Alameda, Santa Clara, San Mateo, and San Francisco Counties.

Notice is hereby given to the general public as follows:

1) A Draft Program Environmental Impact Report (PEIR) on the WSIP has been prepared by the San Francisco Planning Department to identify potentially significant environmental effects of the proposed program, ways to minimize those effects, and feasible alternatives. The report can be viewed online at www.sfgov.org/site/planning/mea (or by linking to this site from http://PEIR.sfwater.org). A printed copy of the report is available for public review and comment at the Planning Department offices at 1660 Mission Street, 1st Floor, Planning Information Counter. A printed copy of the report and associated reference materials are available for review by appointment at the San Francisco Public Utilities Commission by calling 1-866-231-1337 or e-mailing PEIRappointments@sfwater.org. They also can be viewed at:

- Alameda County/City of Fremont Library: 2400 Stevenson Boulevard, Fremont
- San Francisco Main Library: 100 Larkin Street San Francisco
- Stockton-San Joaquin County Public Library: 605 N. El Dorado St, Stockton
- San Mateo County/Belmont Library: 25 Tower Road, San Mateo
- San Jose-Dr. Martin Luther King, Jr. Library: 150 East San Fernando, San Jose
- Tuolumne County Library: 480 Greenley Road, Sonora

2) The Draft PEIR evaluates the environmental effects of the proposed changes in water supply, including growth-inducing impacts, as well as the general environmental effects of implementing 22 facility projects. The analysis in the Draft PEIR finds that the WSIP would support planned growth in the existing SFPUC service area and indirect effects of growth are significant and unavoidable. All other impacts resulting from water supply changes could be mitigated to a less-than-significant level, with the exception of an unavoidable impact on streamflow for about two miles in Alameda Creek and a potentially significant and unavoidable fisheries impact in Crystal Springs Reservoir. The environmental analysis also determined that most of the impacts associated with implementing facility projects could be mitigated to a less-than-significant level, although some impacts in the areas of land use, visual resources, cultural resources, biological resources, noise, vibration, air quality, and traffic were conservatively identified as potentially significant and unavoidable at the programmatic level. These impact determinations may be revised during subsequent environmental review of individual facility improvement projects.

3) Public hearings on this Draft PEIR have been scheduled as follows:

- Sept. 5 6:30 p.m.: Sonora Opera House, 250 S. Washington Street, Sonora
- Sept. 6 6:30 p.m.: Thomas Downey High School Cafeteria, 1000 Coffee Rd, Modesto
- Sept. 18 6:30 p.m.: Fremont Main Library, Fukaya Room, 2400 Stevenson Blvd, Fremont
- Sept. 19 6:30 p.m.: Avenidas Senior Center, 450 Bryant, Palo Alto
- Sept. 20 1:30 p.m. or later: San Francisco Planning Commission, City Hall, Rm 400, 1 Dr. Carlton B Goodlett Place, San Francisco (Call 558-6422 the week of the hearing for a recorded message giving a more specific time).

4) Public comments on the Draft PEIR will be accepted by the San Francisco Planning Department from Friday, June 29 through 5: 00 p.m. on Monday, October 1, 2007. You may submit comments to the Planning Department using any of the following means: provide oral or written comments at a public hearing; mail comments to the San Francisco Planning Department, attention: Paul Maltzer, Environmental Review Officer, WSIP PEIR, 1650 Mission Street, Suite 400, San Francisco, CA 94103; or e-mail comments to wsip.peir.comments@gmail.com. The San Francisco Planning Department will prepare written responses to comments received during the public review period in a Comments and Responses document. If you have any questions about the environmental review of the WSIP, please leave a message for the Planning Department at 1-866-231-1337.

K. Attachment Log

Attachment Log

This attachment log summarizes any attachments received with a particular letter, some of which are included in this Comments and Responses document and others that are available for review at the San Francisco Planning Department. If the attachments contain direct comments on the adequacy or accuracy of the Draft PEIR, they are included along with the comment letters in Chapter 12 and are treated as individual comments. However, in other instances the attachments provide generic information supporting some aspect of an agency or organization's mission (e.g., description of a city's conservation program and activities) and are not directly related to the adequacy or accuracy of the Draft PEIR; those materials are not produced in this document but are available for review at the San Francisco Planning Department.

No More Diversions From The Tuolumne!

keren abra <abra2@mindspring.com> **Mon, Oct 1, 2007 at 1:55 PM**
To: wsip.peir.comments@gmail.com

To:

Paul Maltzer, Environmental Review Officer
Water System Improvement Program PEIR
San Francisco Planning Department

Dear Mr. Maltzer:

I had hoped to attend the hearing on the Tuolumne River plan at City Hall with the Sierra Club recently, and greatly regret that I couldn't do so. My presence may not have made a difference, but I'm expressing to you now my very strong opposition to further diversion of its waters.

Your environmental review of the SFPUC's plan to take more water from the river does not address all the environmental impacts that diversion would cause. I strongly urge you to do additional studies of the Tuolumne before finishing the report.

L-1 I support the alternatives in your draft document that protect the Tuolumne from any new diversions. More water conservation, efficiency, and recycling are the best ways to both protect the River, and provide permanently sustainable water for the San Francisco Bay Area.

Only by keeping a healthy water flow in the Tuolumne can we protect this beautiful river and the diverse watershed and wildlife which depend on it, while at the same time making sure that all future generations in the Bay Area will have access to clean water.

Sincerely,

Keren Abra

Tuolomne water diversion

Thomas Adams <alfadams@earthlink.net> **Tue, Sep 25, 2007 at 4:30 AM**
To: wsip.peir.comments@gmail.com

Paul Maltzer, Environmental Review Officer
San Francisco Planning Department
1650 Mission Street, Suite 400
San Francisco, CA 94103

Dear Mr. Maltzer:

Your environmental review of the San Francisco Public Utilities Commission's plan to take more water from the Tuolumne River fails to adequately identify and address all of the environmental impacts to the River. I urge you to undertake additional studies before finalizing this document.

I support the alternatives identified in your draft document that protect the Tuolumne River from new diversions. Requiring more water conservation, efficiency, and recycling is the best way to lessen impacts on the Tuolumne River while promoting a sustainable water plan for the Bay Area.

Only by ensuring that healthy amounts of water continue to flow into the Tuolumne River can we protect this irreplaceable natural treasure.

Sincerely,

Tom Adams

The Hegelian/Marxist goal is emancipation. Marx said it best in 1843:

"Human emancipation wll only be complete when the real, individual man (sic) is absorbed into himself the abstract citizen; when as an individual man, in his every day life, in his work and in his relationships, he has become a species-being (politically accountabe to the whole); and when he recognizes and realizes his own power as social powers, so that he no longer separates this social power from himself as political power."

Your environmental review of the SFPUC's plan to take more water from the Tuolumne River does not address all environmental impacts to the River. I strongly urge you to do additional studies of the Tuolumne before finishing the report.
I support the alternatives in your draft document that protect the Tuolumne from any new diversions. More water conservation, efficiency, and recycling are the best ways to both protect the River, and provide permanently sustainable water for the San Francisco Bay Area.

Only by keeping a healthy water flow in the Tuolumne, can we protect this beautiful river and the diverse watershed and wildlife which depend on it; while at the same time making sure that all future generations in the Bay Area will have access to clean water.

Sincerely,
Julian Giardinelli

Paul Maltzer, Environmental Review Officer Water System Improvement Program PEIR San Francisco Planning Department

Dear Mr. Maltzer:

Your environmental review of the SFPUC's plan to take more water from the Tuolumne River does not address all environmental impacts to the River. I strongly urge you to do additional studies of the Tuolumne before finishing the report. To solve future water needs at the risk of degrading California's rivers is a mistake. Please reconsider your current plan.

I support the alternatives in your draft document that protect the Tuolumne from any new diversions. More water conservation, efficiency, and recycling are the best ways to both protect the River, and provide permanently sustainable water for the San Francisco Bay Area.

Only by keeping a healthy water flow in the Tuolumne, can we protect this beautiful river and the diverse watershed and wildlife which depend on it; while at the same time making sure that all future generations in the Bay Area will have access to clean water.

Dear Mr. Maltzer:

Your environmental review of the SFPUC's plan to take
more water from
the Tuolumne River does not address all environmental
impacts to the
River. I strongly urge you to do additional studies of
the Tuolumne
before finishing the report.

I support the alternatives in your draft document that
protect the
Tuolumne from any new diversions. More water
conservation, efficiency,

and recycling are the best ways to both protect the
River, and provide
permanently sustainable water for the San Francisco
Bay Area.

Only by keeping a healthy water flow in the Tuolumne,
can we protect
this beautiful river and the diverse watershed and
wildlife which
depend
on it; while at the same time making sure that all
future generations
in
the Bay Area will have access to clean water.

Sincerely,

Sara Meghrouni
1252 5th Avenue
SF CA 94122

To: Paul Maltzer, Environmental Review Officer
Water System Improvement Program PEIR
San Francisco Planning Department

Dear Mr. Maltzer:

I understand from TheCity.org that your organization is responsible for reviewing and approving the diversion and sale of additional Sierra waters to east bay suburbs. I'm personally concerned that with changes to our environment, it's not clear that such supplies will be available in the future and thus there must be strict limitations put on water usage (not just for new developments, but current users--both residential and business/agriculture). Your environmental review of the SFPUC's plan to take more water from the Tuolumne River does not address all environmental impacts to the River. I strongly urge you to do additional studies of the Tuolumne before finishing the report.

I support the alternatives in your draft document that protect the Tuolumne from any new diversions. More water conservation, efficiency, and recycling are the best ways to both protect the River, and provide permanently sustainable water for the San Francisco Bay Area.

Dear Mr. Maltzer:

Your environmental review of the SFPUC's plan to take more water from the Tuolumne River does not address all environmental impacts to the River. I strongly urge you to do additional studies of the Tuolumne before finishing the report.

I support the alternatives in your draft document that protect the Tuolumne from any new diversions. More water conservation, efficiency, and recycling are the best ways to both protect the River, and provide permanently sustainable water for the San Francisco Bay Area.

Only by keeping a healthy water flow in the Tuolumne, can we protect this beautiful river and the diverse watershed and wildlife which depend on it; while at the same time making sure that all future generations in the Bay Area will have access to clean water.

Sincerely,

Kevin Rayhill

Dear Mr. Maltzer:

I am a fisherman and an outdoors man who values our rivers and I stand in solidarity with Palo Alto councilman Peter Drekmeier who is Program Director with the Tuolumne River Trust.

Your environmental review of the San Francisco Public Utilities Commission's plan to take more water from the Tuolumne River fails to adequately identify and address all of the environmental impacts to the River. I urge you to undertake additional studies before finalizing this document.

I support the alternatives identified in your draft document that protect the Tuolumne River from new diversions. Requiring more water conservation, efficiency, and recycling is the best way to lessen impacts on the Tuolumne River while promoting a sustainable water plan for the Bay Area.

Only by ensuring that healthy amounts of water continue to flow into the Tuolumne River can we protect this irreplaceable natural treasure.

Sincerely,

M. Comment Letters Received After December 31, 2007

APPENDIX M

Comment Letters Received After December 31, 2007

The public review period on the Draft PEIR, initially scheduled for 90 days (from June 29, 2007 through October 1, 2007), was extended by an additional 15 days, to October 15, 2007. All comments received through December 31, 2007 were accepted by the San Francisco Planning Department and are responded to in this Comments and Responses document. Comment letters received after December 31, 2007 are presented below; these comments are not responded to individually, but the issues have already been addressed. **Table M.1** includes a cross reference for each of these letters to either a master response or another response that includes a discussion of related issues.

TABLE M.1
COMMENT LETTERS SUBMITTED ON THE DRAFT PEIR AFTER DECEMBER 31, 2007

Comment Letter Format	Name of Commenter	Organization/ Affiliation	Date of Letter	Issues	Pertinent Response
Letter	Arthur R. Jensen, Ph.D.	Bay Area Water Supply & Conservation Agency	02/21/08	Modified WSIP; agricultural conservation	Section 4.10, Master Response on Modified WSIP Alternative
Letter	Arthur R. Jensen	Bay Area Water Supply & Conservation Agency	07/17/08	Phased WSIP Variant; economic impacts of service interruption	Section 13.4, Phased WSIP Variant; Section 14.1, Master Response on WSIP Purpose and Need (Section 14.1.6)
Letter	John Stufflebean	City of San Jose	06/27/08	Phased WSIP Variant; economic impacts of service interruption	Section 13.4, Phased WSIP Variant; Section 14.1, Master Response on WSIP Purpose and Need (Section 14.1.6)
Letter	Alan Kurotori	City of Santa Clara	06/27/08	Phased WSIP Variant; economic impacts of service interruption	Section 13.4, Phased WSIP Variant; Section 14.1, Master Response on WSIP Purpose and Need (Section 14.1.6)
Letter	Keith Whitman	Santa Clara Valley Water District	06/24/08	Phased WSIP Variant; economic impacts of service interruption	Section 13.4, Phased WSIP Variant; Section 14.1, Master Response on WSIP Purpose and Need (Section 14.1.6)
Letter	Emily McGinty	Citizen	02/22/08	No additional Tuolumne River diversions; more conservation and recycling; impacts on San Joaquin River and Delta	Responses C_Form1-01 and -02; Section 14.8, Master Response on Delta and San Joaquin River Issues

BAWSCA
Bay Area Water Supply & Conservation Agency

February 21, 2008

Mr. William Wycko
Acting Environmental Review Officer
San Francisco Planning Department
1650 Mission Street, Suite 400
San Francisco, CA 94103

Dear Mr. Wycko:

The Bay Area Water Supply and Conservation Agency ("BAWSCA") submitted extensive comments last fall on the draft PEIR on the Water System Improvement Program developed by the San Francisco Public Utilities Commission. Those comments expressed BAWSCA's support for the "Modified WSIP" which the draft PEIR identified as the "Environmentally Superior Alternative." We also recommend that the final PEIR evaluate it in more detail.

The Modified WSIP contemplates additional water conservation/recycling in communities in San Mateo, Santa Clara and Alameda counties that currently purchase water from the SFPUC. It also envisions that increased diversions from the Tuolumne River would be offset by water use efficiencies (funded by Bay Area water agencies) in the agricultural lands bordering the Tuolumne River. Our comments were intended to corroborate the feasibility of this concept. They also conveyed the recommendation of the BAWSCA Board of Directors that the final PEIR "explore the feasibility of Bay Area water customers financially supporting water efficiencies in the [Turlock Irrigation District/Modesto Irrigation District] that will result in more water remaining in New Don Pedro than is currently the case, even after taking increased diversions by San Francisco into account." (BAWSCA comments, p. 47)

As further evidence of the feasibility of this approach, I am enclosing the following materials:

- Letter dated February 15, 2008 from Professor Brent Haddad, Director of the Center for Integrated Water Research at the University of California at Santa Cruz, substantiating the feasibility of the agricultural conservation element of the modified WSIP.

- Declaration dated July 23, 2007 by Peter Gleick, President of the Pacific Institute, submitted to the U.S. Federal District Court for the Eastern District of California demonstrating the feasibility of agricultural water users in the San Joaquin hydrologic region implementing additional long-term water management and efficiency measures.

Professor Haddad's resume is attached to his letter. The declaration submitted by Dr. Gleick summarizes his qualifications and experience at paragraphs 1 through 3. A more extensive biographical review is enclosed with this letter.

I have also enclosed a copy of my own resume, which summarizes my academic training and my several decades of experience in planning and managing California water delivery systems, as support for my personal opinion that the agricultural water conservation element in the Modified WSIP is feasible.

I hope this information is helpful to the Planning Department as it prepares a Final PEIR. I trust, and request, that this letter and its accompany materials will be made part of the record prepared for review by the Planning Commission, and by the Board of Supervisors in the event of an appeal from the Planning Commission certification of the Final PEIR.

Sincerely,

Arthur R. Jensen, Ph.D.
Chief Executive Officer and General Manager

Enclosure (s)

1. February 15, 2008 letter from Prof. Brent Haddad, MA, MBA, Ph.D. regarding the feasibility of the agricultural conservation of the modified WSIP.
2. July 23, 2007 Declaration of Peter H. Gleick, Ph.D. to the U.S. Federal District Court of the Eastern District of California.
3. Resume of Arthur R. Jensen, Ph.D., BAWSCA Chief Executive Officer and General Manager.

BRENT M. HADDAD, M.A., MBA, Ph.D.
DIRECTOR, AND
PROFESSOR OF ENVIRONMENTAL STUDIES

February 15, 2008

Mr. Arthur R. Jensen
General Manager
Bay Area Water Supply and Conservation Agency
155 Bovet Road, Suite 302
San Mateo, California 94402

Dear Mr. Jensen:

As you requested, I have reviewed the Draft Program Environmental Impact Report (Draft PEIR) for the San Francisco Public Utilities Commission (SFPUC) Water System Improvement Plan (June 2007, http://www.sfgov.org/site/planning_index.asp?id=37672), as well as the comments on it submitted by the Bay Area Water Supply and Conservation Agency (BAWSCA). My particular focus has been the feasibility of the "Modified WSIP" alternative. Of the three aspects of the Modified WSIP proposal, I address the potential for water conservation and savings in the lower Tuolumne River watershed (LTRW), a region served by the Modesto Irrigation District (MID) and Turlock Irrigation District (TID). Based on my experience with the economics of both urban and agricultural water use in California, it is my opinion that this aspect of the Modified WSIP Alternative is definitely feasible.

The Modified WSIP is described as the "environmentally superior alternative" (p. 9-96). The Modified WSIP can be a source of environmental improvement by providing additional in-stream flows to the lower Tuolomne River while also providing additional water to the San Francisco Bay Area. The Draft PEIR anticipates joint projects involving BAWSCA and SFPUC in the LTRW (9-96), and correctly notes the value of collaboration in reducing overall environmental impacts on the Tuolumne River.

Below, I make the following points:

1. Water "conservation" as used in the Draft PEIR should be understood as water "savings" - the ultimate result of numerous water management strategies and technologies, not just reductions in quantities consumed by a particular end use of water.

2. Water conservation projects (broadly understood) could cost-effectively improve the long-term water supply reliability of the San Francisco Bay Area while simultaneously improving environmental conditions on the lower Tuolumne River through enhanced in-stream flows.

1. The Draft PEIR aims in the right direction by suggesting that water conservation projects yielding year-round supply enhancement can be pursued in the LTRW (Sec. 9-2-8 *Modified WSIP Alternative*; pp. 9-78 to 9-79). However, this categorization specifying conservation only (p. 9-81) is too narrow. Water conservation is typically understood to mean a reduction in end-use of water without loss of amenity or productivity. It is achieved by implementation of less-water-intensive technologies, economic incentives, or both. Narrowly understood, it is only one of numerous water-supply-enhancing strategies now available to water managers. More broadly, conservation simply means saving water: engaging in carefully-considered endeavors that help society achieve numerous goals with limited water supply. This latter understanding of conservation better serves state and regional interests in managing the Tuolumne River system since it provides a broader scope of action to meet the many demands on the system.

Other sections of the Draft PEIR list and comment on numerous water-management strategies proposed for implementation in the San Francisco Bay Area. The same list of management and new-technology alternatives proposed for the San Francisco Bay Area should also be available for consideration in the LTRW. These options include conservation (traditionally understood), water reclamation and reuse, desalination of inland brackish water, storm water management, improved management and retrofits of existing reservoirs and supply infrastructure, and groundwater-surface water management programs. As long as any of these approaches increases available water, improves environmental conditions, improves supply reliability, and is cost-effective, it doesn't matter where it occurs. If the conservation-only language appears in the Final PEIR, I hope it will be understood that conservation signifies a larger category of water-saving endeavors that includes at least the programs and technologies mentioned above.

2. Within the combined natural and engineered watershed of the Tuolumne River, it is possible to identify cost-effective water-saving projects that could provide both additional instream flows on the lower Tuolumne River and additional water to the San Francisco Bay Area. From an economic perspective, one should anticipate the potential for cost-effective agricultural and urban water savings in the LTRW. Water-conserving irrigation technologies have advanced in recent years, as have urban water reclamation and reuse technologies. Effective water-saving technologies such as drip irrigation are now in use in agricultural areas throughout California, on a variety of crops. Many end-users of water in the LTRW have not yet been offered strong financial incentives to implement them. One should anticipate that incentive programs similar to those implemented in Imperial Irrigation District would result in saved water in the LTRW.

The "Water Conservation and Transfer Program" involving Imperial Irrigation District (IID) and the Metropolitan Water District of Southern California (MWD), initiated in 1988, included 15 projects designed to conserve 105,000 acre-feet per year of water in IID's delivery system and on individual farms. District-level conservation projects included lining of earthen canals, constructing local reservoirs, installing spill-interceptor systems and non-leak gates, automating instrumentation and control systems, and altering water-delivery timetables. On-farm conservation measures included tailwater pumpback, drip irrigation, and linear-move irrigation systems. The program's EIR considered impacts on drainage, groundwater, native habitats, runoff, chemicals of concern, and eco-toxicological risks. The IID program, which provided direct economic benefits to farmers in IID, improved IID's infrastructure as well as water supply reliability in the MWD service territory.[i] A subsequent agreement between IID and the San Diego County Water Authority (1998) identified an additional 303,000 acre-feet of on-farm and distribution system conservation projects. These agreements serve as an example of what is possible when introducing positive economic incentives to manage water wisely.

Just as with IID, the LTRW has substantial water-savings capacity. The CALFED publication "Water Use Efficiency: Comprehensive Evaluation" supports the conclusion that efficiency improvements are available in the eastern San Joaquin Valley.[ii] CALFED's Agricultural Water Use Efficiency documentation also finds that potential savings exist in the larger CALFED region from reduced evapotranspiration and improved long-term diversion flexibility.[iii] The CALFED Efficiency Program analysis estimates 185-225 thousand af/year conservation potential for the larger region in which MID/TID is found (Table 5-8b), a region roughly four times larger than MID/TID.[iv] The bulk of the savings are in urban landscaping conservation measures. This suggests a roughly 50 thousand af/year (an average of 70 cfs) conservation potential in the MID/TID region. However, this estimation that does not take into account the range of targeted economic incentives and support for conservation that were successful in IID and are possible in the LTRW. The actual conservation potential in the LTRW is much higher, at least 100,000 acre-feet/year, depending upon the design of and commitment to conservation incentive programs.

MID's 1999 Water Management Plan identifies several potential efficiency activities (Table 43).[v] They include improving the efficiency of MID water supply operations, water reclamation and reuse, and others. Estimated water savings/production are not provided, but appear to be substantial. TID provides the same general information in Table II-1 of its Agricultural Water Management Plan Two-Year Progress Report.[vi]

In terms of urban Best Management Practice savings, the San Joaquin River region is one of the weakest performers in the CALFED territory (Fig 1.3, p. 16). Urban water is roughly 5% of overall water use, but the proportion is growing as urbanization continues.[vii] The 2000 regional population density was just under 200 persons per square mile, mostly concentrated in cities, less than one-tenth of the population densities of the urbanized BAWSCA territories. 1995 regional per capita water use was 301 gallons per day in the MID/TID region, nearly three times the per capita use in the BAWSCA territories. Urban landscape acreage in the MID/TID region is expected to nearly double between 2000 and 2020. Without a system of incentives or regulations to guide landscaping choices, this acreage could become a large water consumer in the coming decades. A lack of available funding for programs of this sort appears to be hindering implementation.

By way of categories, the following general approaches to water supply management should be considered in the LTRW:

1. Surface-water/groundwater Conjunctive Management. This approach could include efforts to improve groundwater quality, as well as desalinating the brackish groundwater in near-surface aquifers in the western portion of the LTRW.
2. Spill and Drainage Recovery and Reservoir Improvement. This approach involves investing in improvements in the MID and TID storage and delivery infrastructures to improve delivery efficiency.
3. Water Reclamation and Reuse. This approach could take the form of (1) improving urban wastewater through advanced treatment to make it available for urban and agricultural reuse in the LTRW, and/or (2) improving agricultural waters, including waters used by the dairy and livestock industries. Water end-use is not reduced, but demand for water taken directly from the Tuolumne River is.
4. Water-Smart Landscaping. This approach provides incentive for urban and residential low-water-use landscaping.
5. Drip Irrigation. This approach reduces demand by farmers for water deliveries.
6. Other Urban Incentives. These include technology retrofits, stormwater capture and use, and low-water-use urban growth planning.

All of these categories have the potential to cost-effectively reduce demand for Tuolumne River water in the LTRW. Water saved could then be used to improve environmental conditions along the Lower Tuolumne River (by providing additional in-stream flows), while also providing additional water supply to the San Francisco Bay Area. Carefully selected programs would not harm the traditional agricultural character of the LTRW, and could support it by providing an additional source of income to the region's agricultural sector.

Please contact me if you have further questions on this topic. A copy of my Curriculum Vitae is enclosed.

Sincerely,

Brent M. Haddad

EMPLOYMENT HISTORY

2007- Founder and Director, Center for Integrated Water Research, University of California, Santa Cruz

1997- University of California, Santa Cruz. Professor of Environmental Studies

1991- Consultant on energy, water, environmental regulation and policy, and market development.

EDUCATION

1996 University of California, Berkeley, Ph.D. in Energy and Resources

1991 University of California, Berkeley, Haas School of Business, MBA in Business and Public Policy

1985 Georgetown University, School of Foreign Service, Washington, D.C., M.A. in International Relations

1982 Stanford University, B.A. in International Relations

SELECTED AWARDS AND HONORS

2007 California Public Utilities Commission, Division of Ratepayer Advocates, research and administrative coordination of a process to identify a regional solution to Monterey County water supply needs, $326,000.

2007 Monterey Regional Water Pollution Control Agency, exploring the federal role in regional water treatment and supply projects. $42,000.

2006 California Public Utilities Commission, Division of Ratepayer Advocates, research support for analysis of the Central California Water Project, $100,000.

2005 California Department of Water Resources Proposition 50 grant competition. "Developing a Tool to Guide State and Local Desalination Planning," $2,597,149.

2003 WateReuse Foundation. Organized and held a research needs assessment workshop entitled, "Integrating Human Reactions to Water Reclamation and Reuse into Reuse Project Design." $30,000.

1998-99 *Excellence in Teaching Award,* University of California, Santa Cruz.

1999 *Educational Service Award,* University of California Educational Partnership Center.

1998-00 University of California Centers for Water and Wildland Resources. "An institutional analysis of the application of urban reclaimed water to agriculture in California." $50,500.

1997-98 University of California Fund for Toxics Research. "Assessing the Early Economic Impacts of the Salinas Valley Reclamation Project and the Castroville Seawater Intrusion Project." $30,000.

PUBLIC LECTURE AND FORUM PARTICIPATION

2007 Legal Seminar on Water Recycling, "Future Potential for Recycled Water," Monterey, California, February 2.

2007 "Report on a Water Reclamation Survey," presented at a meeting jointly sponsored by the City of San Jose and the Government of Queensland, Australia, San Jose, CA, January 28.

2006 Interviewee, "Talk of the Nation Science Friday," NPR (Oct. 13).

2006 Member, Organizing Committee and Scientific Advisory Board, 2007 Dubrovnik Conference on Sustainable Development of Energy, Water, and Environmental Systems, sponsored by UNESCO.

2006 Interviewee, "World of Possibilities" syndicated radio program on the topic of desalination (August 15).

2006 Participant, "Recycled Water…changing public perception and addressing negative branding," hosted by US Bureau of Reclamation and Southern California Water Recycling Projects Initiative, Los Angeles (June 7)

2006 Interviewee, "Which Way L.A.," Los Angeles-based radio program on the topic of water reclamation and reuse (May 17).

2006 Panelist, "Water Reuse & Future Limitations – Pharmaceutical Effects on People and Fish Alike," Washington Association of Sewer and Water Districts (April 21).

2006	Participant, national Joint Water Reuse & Desalination Task Force meeting on institutional issues in desalination and water purification, San Antonio, Texas (April 17-18).
2006	Presenter, Administrative Law Judges Lunchtime Seminar Series, California Public Utilities Commission, "New Directions for California Water Governance," San Francisco (March 16).
2005	"California Water Policy: Planning for Climate Change, Growth, and Natural Heritage Preservation," 25th Biennial Groundwater Conference and 14th Annual Meeting of the Groundwater Resources Association of California, Sacramento (October 26).
2005	Moderator, Panel on Groundwater. California Water Law Symposium. University of San Francisco School of Law, San Francisco, CA. (January 22).
2004	Panelist, Fall Meeting of the Dissertation-Year Fellowship Program and the President's Postdoctoral Fellowship Program, Oakland, Ca. (October 1).
2004	"Global Warming and Environmental Justice," California League of Conservation Voters Environmental Justice Alliance. San Francisco, CA (May 20).
2004	Participant, Workshop on Developing a Water Reuse Economic Framework, sponsored by the National Water Research Institute and WateReuse Foundation. Pomona, CA (May 10-12).
2004	"Not an accident? Understanding Why One Billion People Worldwide Lack Reliable Drinking Water." Inaugural talk of the Synergy Lecture Series. U.C. Santa Cruz Science and Engineering Library (April 27).
2004	Participant, Water Reuse Research Needs Workshop. San Diego, CA (February 2-4).
2003	"Environmental Justice and Urban Water Management," Los Angeles Area Monthly Environmental Justice Luncheon Series, sponsored by The California League of Conservation Voters. Santa Monica, CA (October 30).
2003	PrecipNet research meeting, National Center for Ecological Analysis and Synthesis. Santa Barbara, CA (March 21-23).
2003	"Reporting on the Colorado River and the Salton Sea," U.C. Berkeley Center for Water Resources, sponsored symposium for journalists (March 15).
2003	"Innovations in State Environmental Policy," presented to State Senators and their staffs. U.C. Berkeley (January 23).
2002	Participant, California Water Law and Policy Conference, April 8-9, San Francisco.
2002	Invited speaker, Institute of the Americas H_2O Americas Conference, on the topic of challenges and benefits of water privatization, April 24, San Diego.
2002	"Property Rights, Ecosystem Services, and Climate Change in the Rural West," to the Analysis and Synthesis of Precipitation and Ecosystem Change Conference, National Center for Ecological Analysis and Synthesis (NCEAS), September 5-7.

2002 "Salton Sea: Historical Accident, Modern Enigma," Santa Cruz Museum of Natural History, February.

2001 "Regional Climate Modeling at the District Level," Annual Meeting of the American Water Resources Association, Albuquerque, NM, Nov. 13.

2000 Guest Speaker, "Community Forum" of *Action Pajaro Valley.* Topic: "Meeting the Challenge of Seawater Intrusion in the Pajaro Valley," Watsonville, CA, September 21.

2000 Presenter, "Water Reallocation in Theory and Practice," before the Berkeley Water Working Group. March 3. Presentation is available at: http://www.cnr.berkeley.edu/csrd/html/projects/0004/index.html

2000 "Evaluating Regional Impacts and Adaptations to Climate Change: The Case of California Water," (co-author K. Merritt) presented to the quarterly C-DELSI Meeting, Santa Cruz. May 19.

2000 Featured Guest, *Eco Review* television show, on the topic of watershed management, April 25.

2000 Lectured on *Rivers of Gold*, Capitola Book Café, Capitola, Ca., March 28.

2000 Featured Guest, KUSP Radio talk show, on water reallocation. March 27.

2000 Featured Guest, KSCO Radio "Saturday Morning Agricultural Hour," on water reallocation, February 26.

1998 3-day Workshop on International Water Policy for graduate students of the Monterey Institute of International Studies, October 16-18.

1998 "Water: A Precious Resource," panelist at a community forum on water issues along California's Central Coast," April 29.

1998 "Market-based Water Conservation on the Monterey Peninsula: The Fair-Use Management Proposal," Monterey Bay Regional Studies Seminar Series, April 24.

1998 "Water Marketing in California: an Update," International Water Issues Seminar, University of California, Santa Cruz, February 9.

1997 "Domestic and International Water Quality Issues," Monterey Institute of International Studies, Monterey CA. October 23.

1997 "The Economics of Fresh Water Policy," Natural Resource Economics Class, University of California, Santa Cruz, October 14.

1997 "California Water Marketing: An Alternative Route to Reform," Environmental Studies Board Seminar Series, University of California, Santa Cruz, January 29.

1996 "A New Approach to Reallocating California's Water Resources," Energy and Resources Group Spring Colloquium Series. April 3.

1995 "Links Between Water Science and Water Policy," presented to the course, "Scientific Foundations of International Environmental Policy," Monterey Institute of International Studies, Monterey CA. November 7.

MEMBERSHIPS AND ACTIVITIES IN PROFESSIONAL ORGANIZATIONS

2006- Member, Project Advisory Committee, WateReuse Foundation, Exploring the Value of Reliability Benefits for Reuse and Desalination Projects, WRF 06-002.

2005- Member, Research Advisory Committee, WateReuse Foundation, a national committee that provides long-term advising on the research direction of the Foundation. Reappointed 2007.

2001 Member, Proposal Advisory Committee, WateReuse Foundation Research Program. Attended workshop to making funding decisions for the 2001 Call for Proposals, San Diego, September 7.

1998 Participant, Water Education Foundation 1998 Update on Recent Water Law and Policy, San Diego, CA. July 9-10

NATURAL RESOURCES DEFENSE COUNCIL, *et al.* Plaintiffs, v. DIRK KEMPTHORNE, Secretary, U.S. Department of the Interior, *et al.* Defendants. SAN LUIS & DELTA-MENDOTA WATER AUTHORITY and WESTLANDS WATER DISTRICT; CALIFORNIA FARM BUREAU FEDERATION; GLENN-COLUSA IRRIGATION DISTRICT, *et al.*; CALIFORNIA DEPARTMENT OF WATER RESOURCES, and STATE WATER CONTRACTORS, Defendant-Intervenors.	Case No. 05-CV-01207 OWW TAG DECLARATION OF PETER H. GLEICK, Ph.D. IN SUPPORT OF PLAINTIFFS' PROPOSED INTERIM REMEDIES Date: August 21, 2007 Time: 9:00 a.m. Courtroom: 3 Judge: Hon. Oliver W. Wanger

I, Peter H. Gleick, declare as follows:

1. I am a founding member, and current President, of the Pacific Institute for Studies in Development, Environment, and Security in Oakland, California, created in 1987. I have more than 20 years of professional experience analyzing, assessing, measuring, modeling, and reporting on freshwater issues, with a focus on water-use efficiency. I have a B.S. in Engineering and Applied Science (1978 cum laude and with distinction) from Yale University. I have an M.S. in Energy and Resources (1980) from the University of California, Berkeley. I have a Ph.D. in Energy and Resources (1986) from the University of California, Berkeley. Both of these graduate degrees were given for work on water resources in California. I am an elected member of the United States National Academy of Sciences. In 2001, I was appointed an Academician of the International Water Academy in Oslo, Norway. In 2003, I was awarded a MacArthur Foundation Fellowship for my work on water conservation science and policy. I have served on the California Department of Water Resources Public Advisory Committee for the California Water Plan.

2. The Pacific Institute is a non-profit corporation dedicated to finding solutions to the related problems of regional and global environmental degradation, unsustainable development, and political conflict through interdisciplinary research, policy analysis, and public outreach. We work collaboratively with water users, corporations, environmental and community groups, local, state, and national governments, and international organizations to address water issues.

3. As founding member and President, I have guided and participated in the Pacific Institute's work on California water issues since its inception in 1987. In 1993, the Institute began comprehensive water conservation and efficiency analysis for the State of California's urban and agricultural sector, including residential, commercial, industrial, and institutional water use, and we published an analysis of this in 1995.[1] I served as a Science Advisory Expert for the CALFED Independent Review Panel on Agricultural Water Conservation Potential in 1998. In 1998, we were contracted by the U.S. Department of the Interior to conduct an independent review of the water-use efficiency analyses of CALFED.[2] In 2003, the Institute published a report on the potential for urban water conservation and efficiency statewide.[3] The results of this work have been adopted in state water planning documents, including the 2005 California Water Plan, and the work of the Planning

and Conservation League. Local water agencies and organizations have requested that the Institute expand this work to address local water concerns. In September 2005, the Pacific Institute released a new study with an analysis of a "high efficiency" scenario for California urban and agricultural users to the year 2030.[4] I was the lead author of this study.

4. This declaration will address three main issues: the kinds of natural and human-caused variations in water supply that face California water users; the ways they have responded to those variations in the past; and the potential for future responses to changes in water availability. The conclusion of my analysis is that substantial reductions in water demands from the Delta are possible in both the short-term and long-term, and that these reductions can be made cost-effectively, with existing technologies and oft-used water strategies. In formulating this declaration, I have considered the materials specifically identified in the endnotes to this report.

5. Water users throughout the State of California are faced with natural wet and dry variations in water supply associated with the natural hydrologic cycle. Increasingly, human factors are playing a role in water supply reliability, including growing competition among users and efforts to restore natural ecosystems by returning water allocations to them, or altering the timing of existing withdrawals.

6. California water users have demonstrated the ability to develop and implement creative and collaborative responses to these variations, including especially a wide range of "conservation" and "efficiency" actions that permit both temporary and permanent reductions in water use. These include changes in technology and policy. Indeed, these actions are considered the foundation of future water policy for the State of California, as described in the most recent California Water Plan from the Department of Water Resources, which states:

> The water plan provides a Framework for Action, or roadmap, that lays out the role of State government and the water community to ensure that California has sustainable water uses and reliable water supplies in 2030 for all beneficial uses. *The framework identifies three foundational actions—use water efficiently, protect water quality, and support environmental stewardship—that will ensure sustainable water uses.* These foundational actions must be central to California water management.[5] (emphasis added)

7. Conservation and efficiency policies and technologies are not merely hypothetical approaches to increasing water savings; they are proven effective tools for reducing demand over time. For example, total water use in California was less in 2001 than it was in 1975 according to the U.S. Geological Survey national water use reports, yet population increased by nearly 60 percent and gross state product increased 2.5 times during this period. Forty years ago, we used nearly 2000 gallons for every person in the state every day. Today, we use half that amount.

7a. Although Californians have improved efficiency of our water use over the past 25 years, current water use is still wasteful. The research I have directed at the Pacific Institute for 20 years concludes that there is substantial untapped potential for both urban and agricultural water users that receive water from the Sacramento-San Joaquin river basins to permanently reduce wasteful uses of water and improve their water-use efficiency. There is also the potential for temporary, shorter-term conservation actions that can reduce water demands.

7b. The Pacific Institute's 2003 report ("Waste Not, Want Not"), funded by California foundations and state water agencies and extensively peer reviewed, provides a comprehensive statewide analysis of the conservation potential in California's urban sector. This study funds that existing, cost-effective technologies and policies can reduce current (year 2000) urban demand by more than 30 percent. The Institute's report "California Water 2030: An Efficient Future" found that similar, substantial savings are available from the agricultural sector as well. More than 65 percent of all crops in California are still grown with inefficient flood or sprinkler irrigation systems. Studies have shown, as cited in that report, that installing efficient irrigation technology such as drip systems can reduce water use and increase agricultural yields. Given that the agricultural sector is responsible for consuming around 80 percent of Californian's use of water, even small efficiency improvements can produce tremendous water savings. Additional water savings are possible if farmers continue to the trend of moving away from water-intensive crops like cotton, pasture, rice, and alfalfa in favor of more valuable, low-water crops like many vegetables, fruits, and nuts.

8. Research from the Pacific Institute and data available from the State of California and California water users also shows that water users in the San Joaquin and Sacramento hydrologic regions, or in regions that use water exported from these watersheds, have not fully implemented

long-term water management and efficiency measures used by similarly situated water users that also face potential water shortages. There is additional potential for both agricultural and urban water users to reduce demand on a temporary basis through short-term actions, some of which can be implemented at little or no cost.

Defining "Water-Use Efficiency" and "Water Conservation"

9. A wide range of water-management actions are available to lessen the effect of any reduction of water supply. Two broad management responses are the focus of this declaration: (1) "efficiency" responses focused on reducing demand by permanently improving the efficiency of existing agricultural and urban uses; and (2) "conservation" responses focused on reducing diversions and pumping requirements by temporarily changing uses or behavior.

10. There are many and varied definitions of "water-use efficiency." In this declaration, improving "water-use efficiency" refers to the potential to provide the same beneficial use to water users while utilizing less water, *i.e.*, to reduce the water needed to do a specific task or satisfy a specific need. Examples include crop shifting while producing the same or more income, replacement of inefficient irrigation methods to boost yields per unit water (or to boost income per acre, or income per gallon), replacement of inefficient water appliances, removal of outdoor water-intensive landscaping in commercial, residential, and institutional settings, and changes to industrial and commercial water processes. Efficiency improvements can be measured and evaluated at the field, crop, household, or business level, or at a larger "basin" level. The focus here is to reduce the use of water that is not used productively to produce a good or service.

11. In this declaration, water "conservation" refers to the additional potential to cut water use by changing benefits, goods, and services. Examples include single-season crop shifting, fallowing, and land retirement for agricultural users, and eliminating lawn watering, taking shorter showers, reducing car washing, and comparable urban actions commonly applied during severe droughts as voluntary responses.

12. Both approaches may be appropriate in certain circumstances, such as drought, temporary or intentional cutoffs of water supplies resulting from changes to operations of the Delta pumps, and changes in allocations.

Discussion and Analysis

13. Water availability naturally fluctuates with wet and dry extremes around the long-term average. Water districts and users may also experience significant short-term reductions in water allocations due to political, economic, or technical factors. Perhaps the most important function of water agencies and irrigation districts is to help water users manage these fluctuations through the development of water supply infrastructure and management practices.

14. These actions are also at the heart of official California water policy. As described in the latest California Water Plan, their official Framework for Action identifies "*three foundational actions—use water efficiently, protect water quality, and support environmental stewardship.* Describing "use water efficiently," DWR goes on to say:

> To minimize the impacts of water management on California's natural environment and ensure that our state continues to have the water supplies it needs, *Californians must use water efficiently to get maximum utility from existing supplies.* Californians are already leaders in water use efficiency measures such as conservation and recycling. Because competition for California's limited water resources is growing, we must continue these efforts and be innovative in our pursuit of efficiency.
>
> Water use efficiency will continue to be a primary way that we meet increased demand. In the future, we must broaden our definition of efficient water use to include other ways of getting the most utility out of our groundwater and surface water resources and water management systems: Increase levels of urban and agricultural water use efficiency...[6]

I. Agricultural Use

15. Growers understand their sensitivity to climatic variability and supply uncertainties, and they understand the value and potential of improving efficiency. A survey by the Center for Irrigation Technology at California State University, Fresno, asked growers "What contingency plans do you have in the event of a prolonged drought?" Growers responded with a wide variety of tools, but the answer chosen more often than any other was "improve system efficiency," showing that the potential to do so is not only there, but considered their first choice. The next two listed were "develop a deficit irrigation plan" and "modified cropping plan."[7]

16. A practical example of the historical capacity to act in the face of supply shortfalls is the Westlands Water District (the largest member of the San Luis and Delta-Mendota Water

Authority). Like other water agencies, Westlands experiences allocation reductions on a somewhat regular basis due to the natural variation in California's water supply and its position as a junior water right holder. During the severe 1987-1992 drought in California, reductions in the delivery of federal surface water from the Central Valley Project (CVP) to Westlands were as large as 70 percent. During this drought, growers within the Westlands Water District responded to water-supply changes by using both conservation and efficiency tools including:

A. Short-term replacement of lost surface supplies with other sources including water marketing, transfers, and increased groundwater pumping,

B. Short-term fallowing of lower valued crops.

C. Long-term permanent improvements in the efficiency of their water use.

D. Long-term changes in crop types.

These actions, described in detail below, are common to all water agencies or districts, including urban agencies, and help reduce the economic and employment impacts of those reductions.

Short-Term Changes in Water Supplies

17. As Figure 1 shows, Westlands relies on a mix of sources of water over time. While CVP water is the dominant source, the District also uses groundwater, transfers from other Districts and users, and other supplies. As the availability of federal surface supplies changes up and down, their reliance on other sources also changes up and down to compensate.

///

///

///

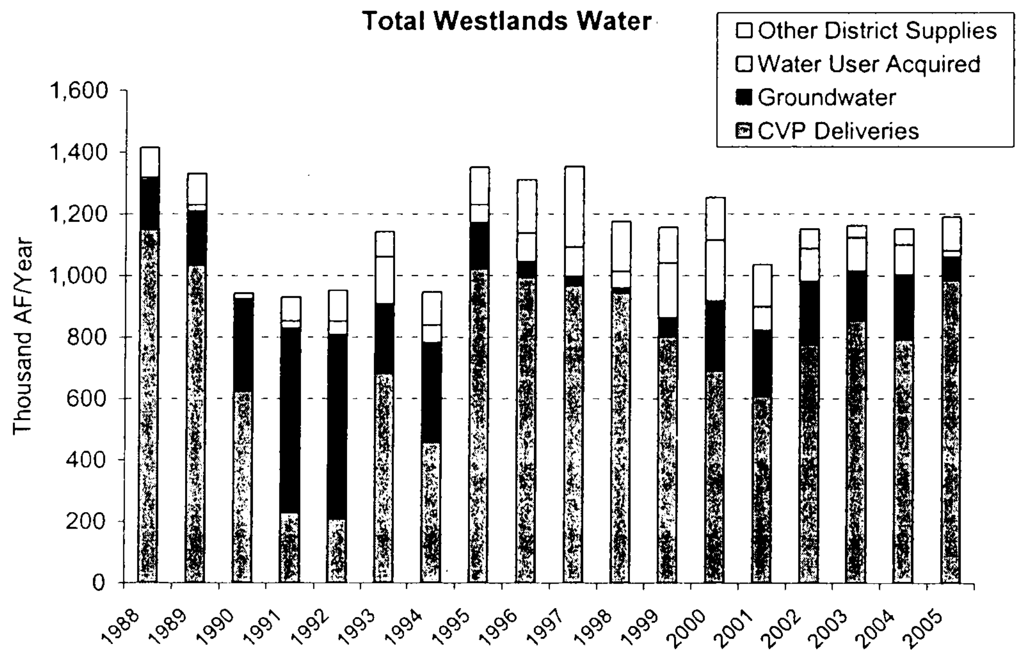

Figure 1. The use of water by the Westlands Water District from 1988 to 2005, showing the source of water. Data come from the Westlands Water District.[8]

18. The option of temporarily relying on increased groundwater pumping is a particularly important one: Central Valley growers regularly rely on short-term increases in groundwater pumping in dry years. Using Westland's data, Figure 2 shows that during the 1987-1992 drought period, CVP surface water deliveries to Westlands dropped approximately 70 percent, from an average of 1,150,000 acre-feet ("af") per year to nearly 300,000 af per year. To make up this shortfall, groundwater pumping increased from 160,000 af per year to 600,000 af per year and has now dropped again during the recent wet years. Particularly when groundwater levels are relatively high (as is currently the case), farmers can pump additional groundwater for very little cost. The current drought has increased groundwater withdrawals to make up for reduced surface supplies – precisely what managed groundwater is intended to do. Similarly, the expansion of groundwater recharge and innovative water banking arrangements made by water districts in Kern County with MWD and other Delta customers, were designed to help buffer drought impacts for both urban and agricultural users.

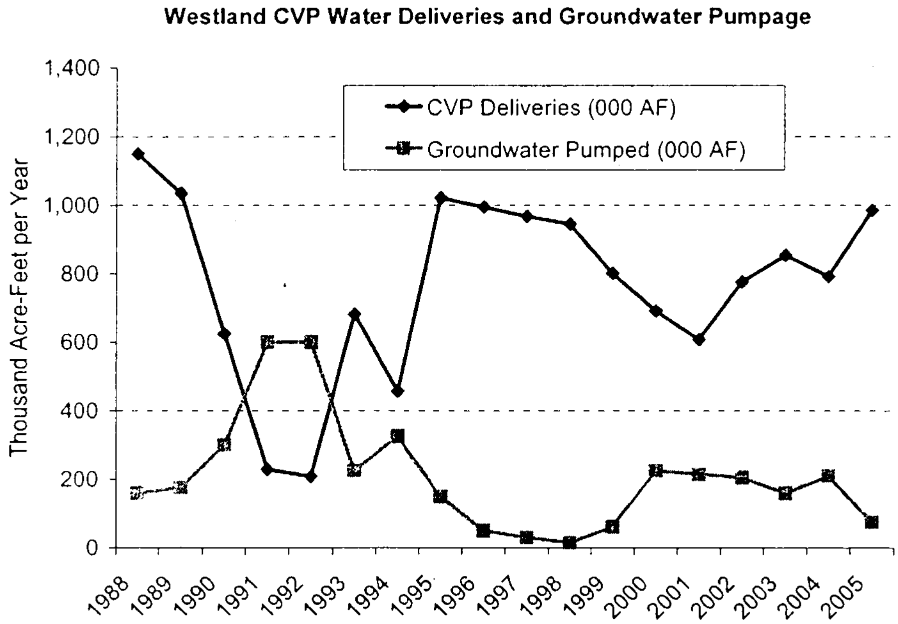

Figure 2. Groundwater and surface water use by Westlands Water District. During the drought of the late 1980s and early 1990s, surface water deliveries dropped and groundwater pumping increased substantially. Groundwater pumping in recent years has dropped back to around or below 200,000 acre-feet per year.[9]

19. There is the risk that increased pumping, even if temporary, could cause long-term environmental impacts, reduced groundwater storage capacity, and land subsidence in some regions, but in many basins in the Central Valley careful conjunctive use of surface and groundwater is common. As Figure 3 shows, high rates of groundwater pumping by Westlands lead to drops in groundwater levels, but groundwater levels recover when pumping declines. Indeed, at present, groundwater levels are relatively high, showing that groundwater is again readily available for use in an emergency drought, for emergency shutdown of surface deliveries, or for other needs. Water districts in Kern County, including KCWA, Semi-Tropic, and Arvin Edison have also developed large water banks to store surface supplies for later use in dry years. These districts have access to multiple supply sources, including local water, state water project supplies, and the San Joaquin River watershed, and have stored large amounts of water in the recent wetter years.

///

///

///

///

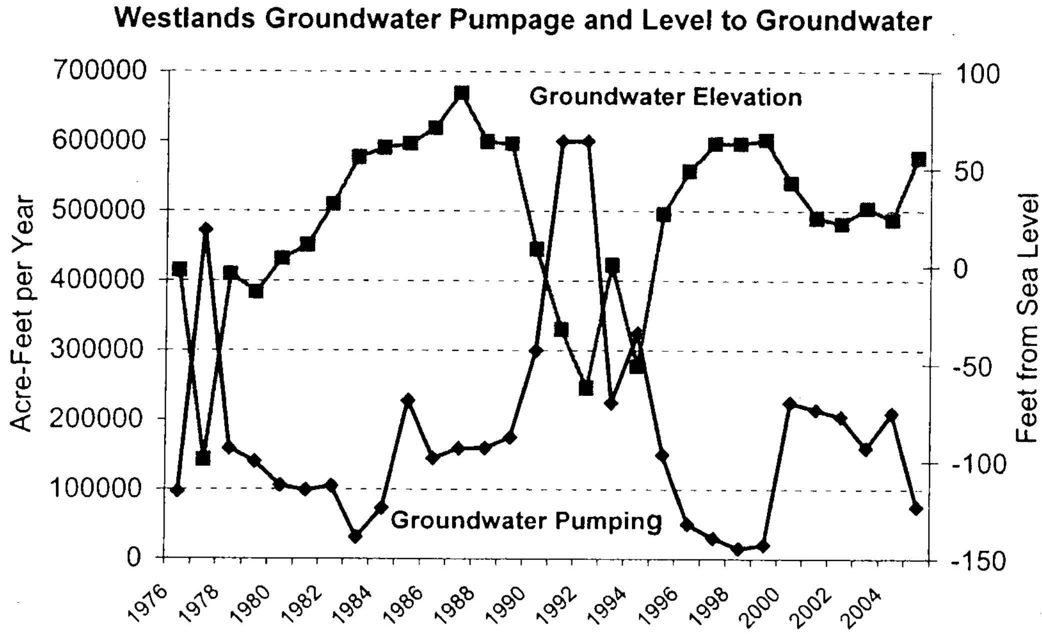

Figure 3: Groundwater pumping volumes (acre-feet per year) and groundwater levels (elevation in feet from sea level) over time for the Westlands Water District. Groundwater levels may drop during high pumping periods but recover during wetter periods. Current groundwater levels are high.[10]

Short-Term Fallowing of Lower-Valued Crops

20. In addition to longer term efficiency improvements, agricultural water users have the potential to implement shorter-term reductions in water use. For example, they can fallow land during severe droughts, reducing total agricultural water demand. All water districts typically fallow some land every year as part of regular rotations, but large amounts of fallowing are usually considered only as a last resort. Any policies encouraging such fallowing must also consider the economic impacts of such policies. This option is comparable to short-term cutbacks in urban water use that occur during extreme shortages.

21. Data from Westlands Water District show that some fallowing always occurs, even during wet years, and that farmers are unlikely to substantially fallow land even during very dry years – preferring instead to find other sources of water (see section A, above), change crop type, or improve efficiency. Figure 4 shows that Westlands growers may fallow as much as 125,000 acres during dry years, but even in the recent wet years over the past decade have typically fallowed between 50,000 and 100,000 acres.

21a. Other water districts have similar options. For example, the San Joaquin River Exchange Contractors currently make up to 150,000 acre-feet per year of their water supply available for sale or exchange with other users.[11] The NEPA/CEQA review of this program notes that the Exchange Contractors have developed this supply largely through conservation efforts (up to 100,000 acre-feet), with additional contributions through temporary land fallowing and idling crops.[12]

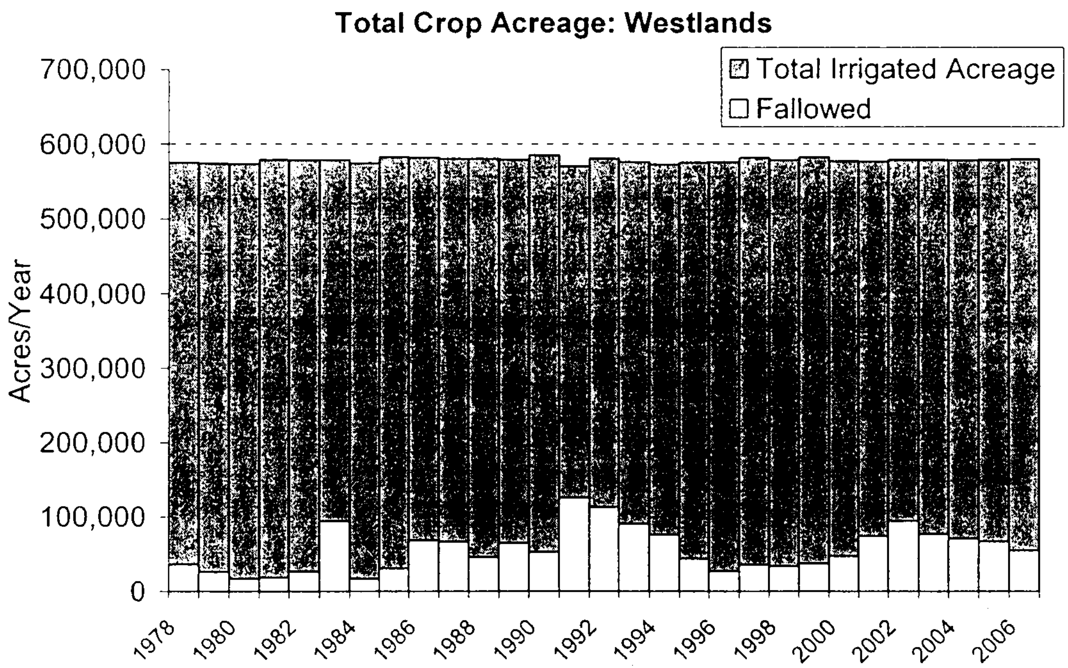

Figure 4: Total irrigated and fallowed acreage in the Westlands Water District from 1978 to present.[13]

Long-Term Improvements in Agricultural Water-Use Efficiency

22. Water is not used as efficiently as possible by Delta water users, even given current economics and technologies. This is one of the major conclusions of State of California analyses and the work of the Pacific Institute.[14] One of the most important arguments in support of the conclusion that improvements in the efficiency of water use are possible comes from growers themselves. A survey of more than 400 growers in the San Joaquin Valley, conducted by the Center for Irrigation Technology at California State University, Fresno, very clearly notes that farmers *themselves* understand that they can do more with the water they have, or even reduce current uses.

In some ways, this is the clearest evidence of the potential to use water more efficiently – academics can argue about data and methods, but farmers themselves have a strong sense of what is possible in their own fields. In this survey, 436 growers responded to the question, "do you irrigate as efficiently as you think you could." *Forty percent* of these growers responded "no" and indeed they offered a list of many dozens of different ways they felt they could improve irrigation efficiency.[15]

23. There has been a substantial change in irrigation type throughout California, permitting increased yields, increased water-use efficiency, and reduced water applied per acre for many crops. In particular, California growers are slowly but consistently moving toward more efficient irrigation methods. Figure 5 shows statewide changes in irrigation method applied to vegetable crops between 1972 and 2001, as reported by DWR surveys. These surveys show that drip irrigation overall has been increasing at a rapid rate, while less efficient gravity/surface irrigation has been declining.[16] Figure 6 shows the same trend statewide for all cropland in California. This trend is likely to continue and could be further accelerated by appropriate policies. Drip irrigation can boost crop yields and production while reducing overall water use. *See* Appendix.

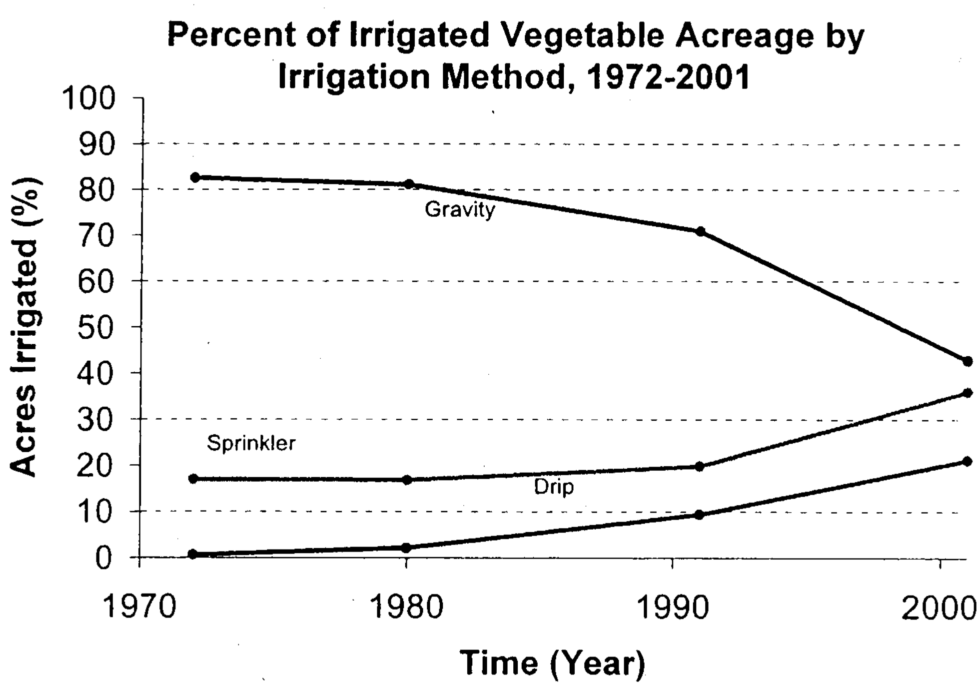

Figure 5: Percentage of vegetable crop area irrigated with gravity, sprinkler, and drip systems for 1971, 1980, 1992, and 2001 from the California Dept. of Water Resources, showing changes in irrigation method over time toward more water efficient systems. The 2001 survey is the most recent statewide.[17]

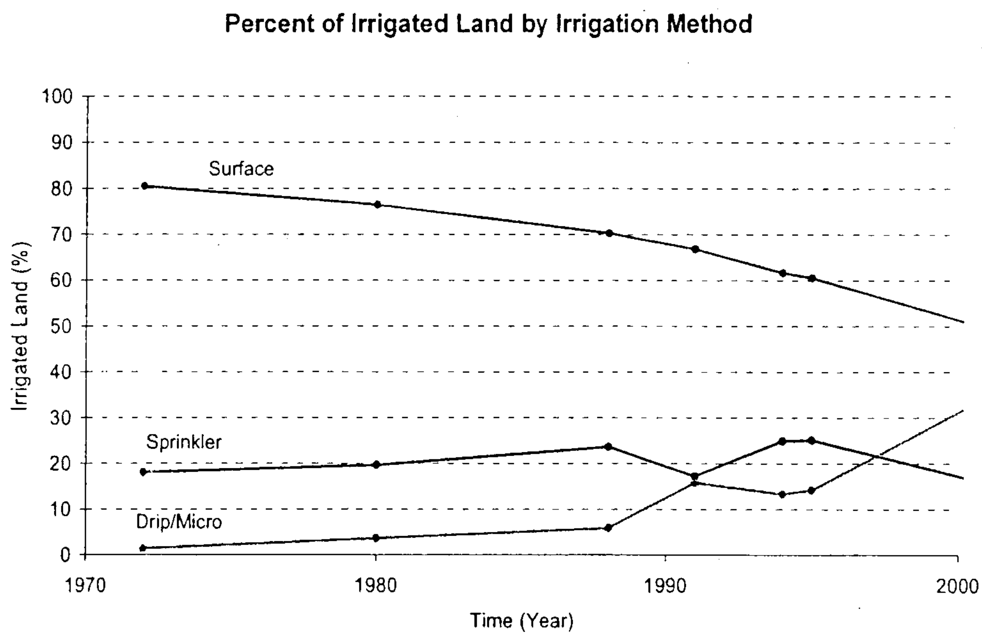

Figure 6: Historical data on the percent of irrigated land (all crops) under each irrigation method between 1972 and 2001. (Data from California DWR surveys and Orang et al. 2005.)[18]

24. The change toward more efficient irrigation methods has been slower in the San Joaquin and Sacramento Valleys than statewide. For example, Figure 7 shows the irrigation methods used on field crops statewide, and in the San Joaquin and Tulare hydrologic regions, according to the Department of Water Resources.[19] As this graph clearly shows, the San Joaquin and Tulare regions are still relying on more wasteful surface irrigation methods, and have shifted more slowly than other parts of the state to more efficient sprinkler systems.

25. At a hydrologic level, the Tulare Lake and San Joaquin regions apply water less efficiently than the state average for all crop types. Surface irrigation is used on 95 percent of field crops in the Tulare and San Joaquin hydrologic regions, compared to 87 percent in the State on average. For vineyards, the difference is even greater: 45 percent of vineyards in the Tulare Lake and San Joaquin hydrologic regions are irrigated with less-efficient surface methods, compared to only 21 percent in the State as a whole. For orchards and vegetables, the San Joaquin and Tulare Lake regions are slightly less efficient than the state average.

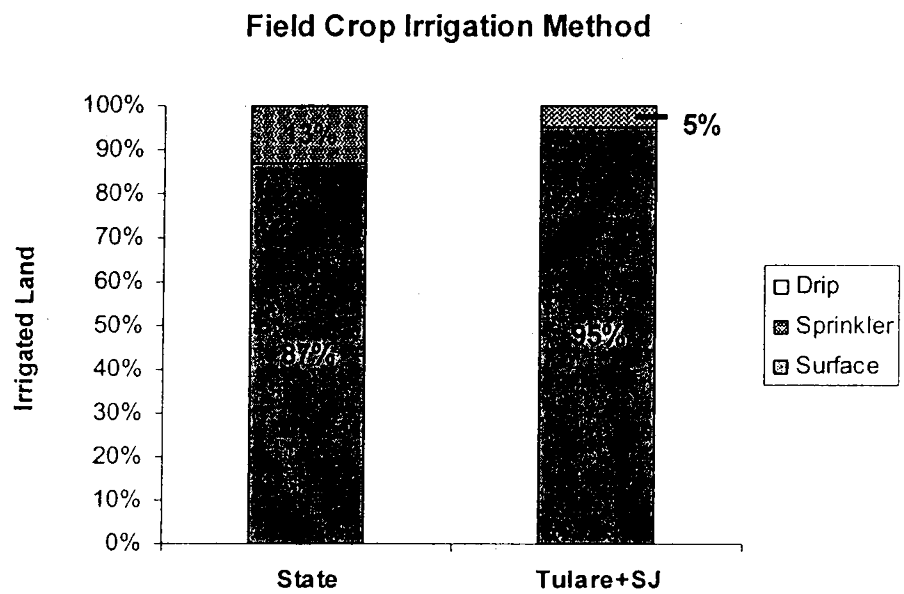

Figure 7. Percent of field crops statewide and in the Tulare and San Joaquin (SJ) hydrologic regions under drip, sprinkler, and surface irrigation, in 2001. Less efficient technologies are used more frequently on field crops in the Tulare and San Joaquin regions than statewide.[20]

26. While it is difficult to accurately measure unproductive evaporation, it is quite clear that such wasted water exists in all irrigation systems. For example, "most measurements have shown spray evaporation and drift to range from 5 to 20 percent of the water discharged."[21] In a series of field-level water balances, Molden found that evaporation losses accounted for 17 percent of total depletion in wheat crops and 30 percent in cotton crops.[22] Hillel estimates that, under surface flood irrigation, 20 to 30 percent of applied water is lost to evaporation from open water surfaces and transpiration by weeds.[23]

27. There are a number of different ways to reduce unproductive evaporation losses. It is widely understood that changing irrigation frequency, irrigation method, mulching, shading, and so forth can modify evaporation.[24] Unproductive evaporation can be reduced without adversely affecting crop production, soil quality, or yields. For example, some water is lost to winds immediately during and following field application. Changing irrigation technology has been shown to have a major effect on reducing evaporative wind losses while maintaining or improving crop yields. Efficient crop maintenance is also important: a well-watered crop with dry soil and plant

surfaces (full cover, no weeds) requires less water than a well-watered crop with wet soil and plant surfaces and weeds in between plants.

28. Irrigation methods that introduce water directly into the root zone, such as drip irrigation, without sprinkling the foliage or wetting the entire soil surface minimize deep percolation, surface runoff, and unproductive evaporative loss, while surface application induces depletion by evaporation. Drip irrigation offers the additional benefit of keeping the soil surface between the rows of crop plants dry, discouraging the growth of weeds that compete with the crops for nutrients and moisture.[25] Evaporation can also be reduced by improving irrigation timing and providing the crops with water when they need it most. For example, there is a greater potential to reduce ET during the midday when transpiration is reduced and evaporation is at its highest. Improvements in irrigation technology and irrigation management can both decrease evaporative losses.

29. According to Piper and Cappelluci, efficient irrigation systems tend to increase crop yield or decrease crop production inputs, an effect noted by many others as well.[26] Bernardo and Whittlesey reported that the potential for conserving water without greatly affecting producer income runs up to 35 percent for surface irrigation and up to 25 percent under center pivot irrigation.[27] Because a substantial amount of irrigated land in the Central Valley is still irrigated with surface or sprinkler methods, these results suggest that total crop yields can be maintained or improved with a smaller input of water; or conversely that crop yields can be significantly boosted with the water currently being used by the agricultural sector. Recent experience with precision irrigation systems in California supports this conclusion (see Appendix).

30. Reductions in evaporation can also be achieved by reducing surface water exposure, evaporation from soils, and mis-application of irrigation water. Indeed, the switch from surface flooding/gravity irrigation to sprinklers or precision drip systems is done in part to reduce this unproductive evaporative loss of water.

31. These data suggest that if growers in Central Valley districts improved irrigation technology even up to the current state average, water savings would result. Moreover, irrigation efficiency can be significantly improved beyond current state average levels.[28]

Long-Term Changes in Crop Type

32. A fourth option regularly employed by growers in response to the perception or imposition of long-term changes in water conditions is changing the type of crop grown. As water becomes more expensive or scarcer, farmers often switch to higher-valued, lower water-using crops.

33. In California agriculture, approximately half of all water used goes to grow rice, cotton, alfalfa, and irrigated pasture. Yet these four crops typically only produce 5 percent of total agricultural revenue, according to data from the California Department of Water Resources.[29] This vast mismatch in economic productivity of water use is driven by many factors, including water availability, pricing, federal subsidies, soil conditions, and the experience of growers with particular crops and equipment.

34. Discussions of crop switching (i.e., growing different kinds of crops on the same land) have traditionally been excluded from California water policy debates. Yet such changes in cropping patterns over time in California have probably had a greater impact on total agricultural water demand, water quality, and consumptive use than any other factor. Policies aimed at encouraging more water-efficient crops could have very large long-term benefits for the California water balance without adversely affecting farm income, and there is evidence that such changes can improve farm income.[30] For example, an analysis from the Pacific Institute shows that crop revenue could actually increase overall by switching a modest amount of acreage out of rice, cotton, alfalfa, and pasture to higher-valued crops, while saving as much as 1.5 million acre-feet of water.[31]

35. Figure 8 shows the shift in the Westlands District away from field crops toward less water-intensive vegetable crops over the past 35 years. As the figure shows, acreage planted in fruits and vegetables has tripled, while acreage planted in water-intensive cotton and other field and row crops has dropped enormously. Yet total agricultural income has more than tripled over the past 30 years to over $1 billion annually.[32]

///

///

///

///

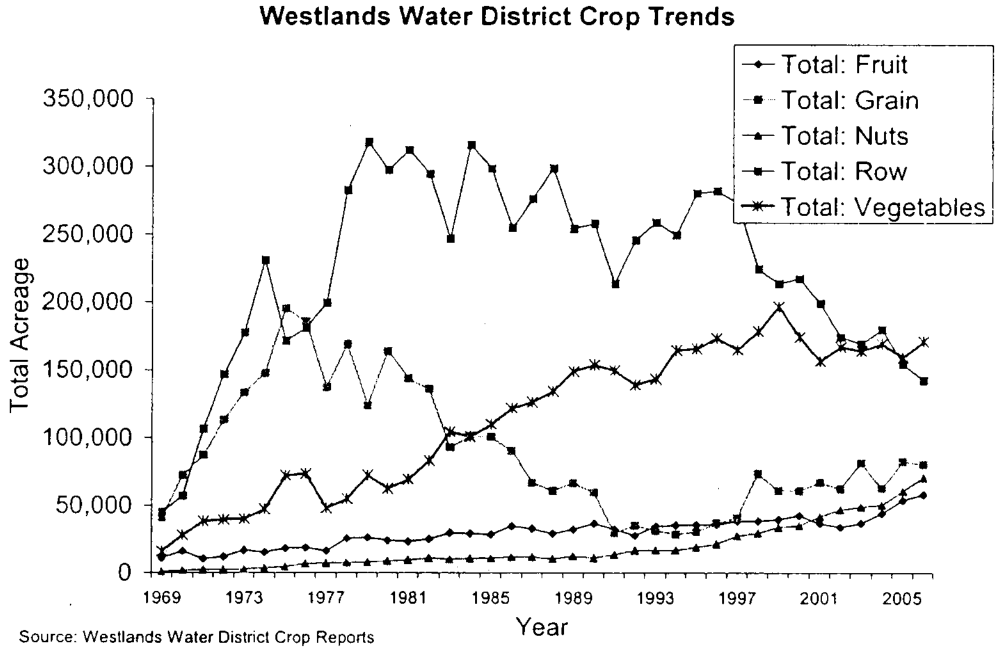

Figure 8: Trends in crop types grown in the Westlands Water District from 1969 to 2006. Total row and grain crops are slowly but consistently being replaced with higher valued, lower-water using fruit, nut, and vegetable crops.[33]

36. There has a similar trend over the past 20 years in the Friant Division away from grain and field crops toward more profitable vegetables, orchards, and vineyards. Figure 9 shows the historical trends in crops planted in the Friant Division between 1987 and 2004. While total crop area has not changed during this period, significant crop shifting has occurred; field crop acreage has declined by 20 percent, whereas vegetable and vineyard acreages have increased by 11 percent and orchard acreage has increased by 26 percent. Orchards and vineyards now account for over 60 percent of the crop area.

///

///

///

///

///

///

///

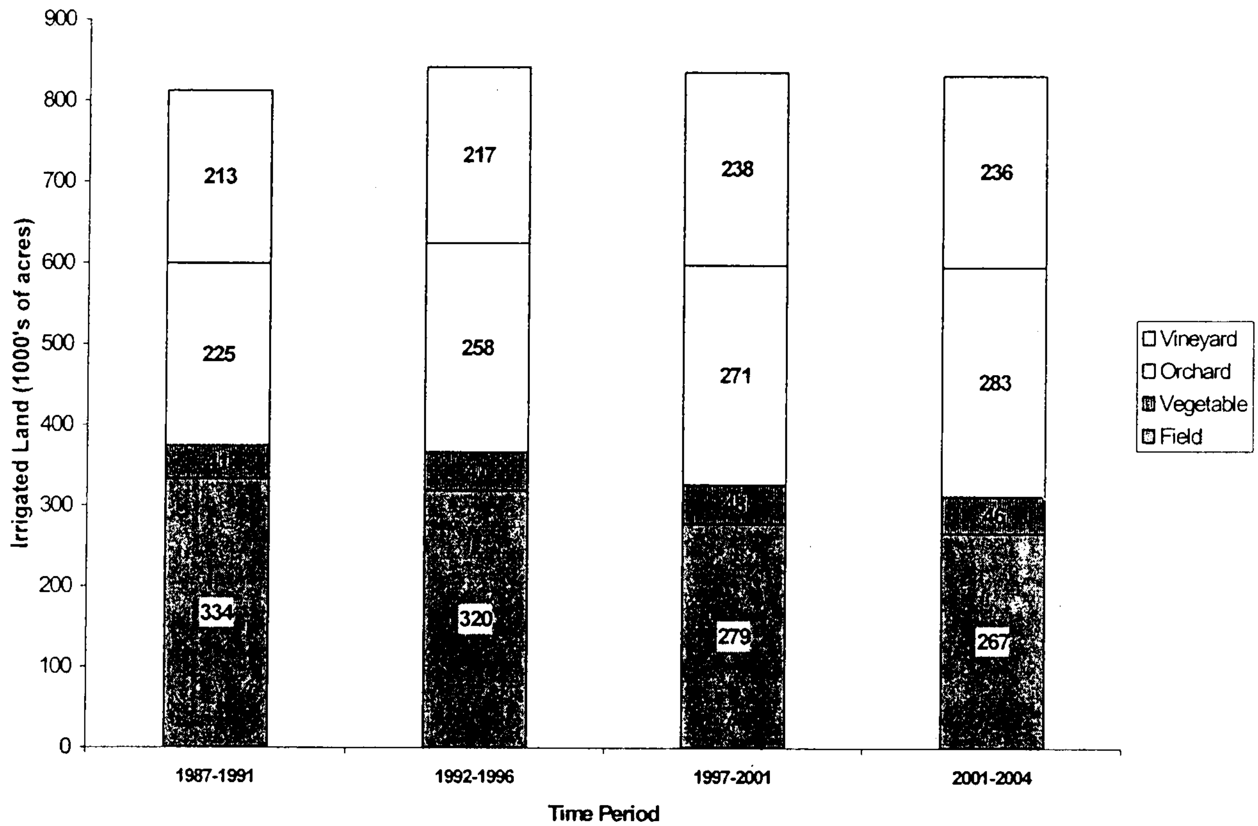

Figure 9: Irrigated acreage in the Friant Division by major crop type between 1987 and 2004.[34] Area devoted to orchards and vineyards is growing; field crop area is decreasing.

37. There is no reason to believe that this trend will stop, and many reasons to believe it will continue or even accelerate. These include:

- Growing pressures on water availability, which encourage growers to plant crops with lower water demands, or permanent crops likely to be given higher water priority during droughts;
- Higher profit for food crops, which can be grown productively on California farmland;
- The ability to better control evaporative losses using precision irrigation, which is more suited to orchards, vineyards, and row crops than low-valued field and grain crops.

38. Crop shifting trends suggest that the potential for water savings may be even greater in the future. Although studies have shown that drip systems apply water more efficiently than

surface irrigation for field crops, the adoption of this technology for field crops has been slower than for other crop types.[35] Over 50 percent of orchards and vineyards statewide are irrigated with drip, while less than one percent of field crops are irrigated with drip. Thus as agricultural land in the Friant Division is converted to higher-value orchards and vineyards, overall water needs will go down, and the ability to install even more efficient irrigation systems goes up.

39. Finally, even without changes in the actual crop types planted in California, we expect to see the introduction of new varieties of crops that are more water-efficient. Traditional crop genetics and efforts to develop new crop varieties with advanced genetic engineering are likely to permit increasing crop yields with either similar or lower water requirements in the future.

II. Urban Use

40. Urban water use in the some of the regions dependent on the Delta is also substantially higher than in other regions of California, largely because of wasteful outdoor landscape irrigation in the hotter climates of the Central Valley and inland areas of Southern California and the Bay Area. Similar to agriculture, urban water savings in areas outside of the Delta export regions can free up water that in many cases can be transferred to Delta users. These outdoor water uses are not critical for health and well-being, and could easily be reduced temporarily (during a short-term emergency) or permanently (through changes in garden irrigation methods, landscape design, and management). Table 1 shows the high average total urban water use per person for the Sacramento, San Joaquin, and Tulare hydrologic regions, compared to the State average. The Table also shows that residential water use in these regions is higher than the State average, including both indoor and outdoor use. A comprehensive assessment of the potential for improving urban water use in the state as a whole showed that total urban needs can be satisfied with about 30 percent less water, simply by applying existing cost-effective water-efficiency technologies.[36]

41. Urban users can also respond to shortages in the short-term through behavioral changes such as taking shorter showers, using dishwashers and washing machines only when full, reducing unnecessary water use when shaving or teeth cleaning, etc. Urban water users can respond quickly to supply shortages caused by drought and the need to provide additional water for the

environment. In the early 1990s, the City of Los Angeles reduced water usage over 100,000 acre-feet in a year (17 percent reduction) as the drought continued and legal efforts to reduce diversions from the Mono Lake Basin succeeded and users became aware of the need and ability to protect ecosystems.[37]

Table 1: Urban Water Use is High in Central Valley Regions

Region	Total Urban Water Use (Gallons per Person per Day)	Residential Water Use (Gallons Per Person Per Day)
Sacramento Region	296	177
San Joaquin Region	312	220
Tulare Region	310	242
State Average	**233**	**145**

Data from the California Department of Water Resources (DWR). 2005. The California Water Plan Update. Public Review Draft (May 2005). Bulletin 160-05. Sacramento, California. Volume 3.

42. Data on specific regional urban uses in the parts of the Central Valley such as the Friant Division service area support the conclusion that comparable, and even greater, water savings are possible here. While Friant service area users get little water from the Delta, it can be a source of water for Westlands and other water users who depend on Delta water. They are, therefore, a potential source of water transfers in any future water management arrangement.

43. According to the California Department of Water Resources California Water Plan, current urban use (per person) in the Tulare Lake hydrologic region is around 310 gallons per person per day. Similarly, regional average per capita urban use in the San Joaquin River hydrologic region is around 304 gallons per person per day.[38] These levels are substantially higher than average statewide use. In part, this higher use is the result of the failure of major cities in the region from Sacramento to Fresno to meter household water use. Such meters have been shown to reduce urban water use when combined with rate structures that charge based on the volume of use.

44. It can be argued that urban water use is higher in these regions because of the warmer, drier climate, and larger average garden and lawn size. This is partly true, but when I correct for this difference and simply look at average indoor residential water use alone, the urban areas in this region still use substantially more water per person than the statewide average. Table 2 shows this comparison. As this Table shows, the state average of indoor residential water use is

Page 21 is missing - did not receive from the commenter.

I declare under penalty of perjury that the foregoing is true and correct to the best of my knowledge. Executed in Oakland, California, on July 23, 2007.

Appendix to the Declaration of Peter H. Gleick

Drip Irrigation Water Savings: Selected Case Studies [1]

- In Los Banos in Fresno County in the late 1990s, Trecho Farms began using subsurface drip irrigation to grow fresh market and processing tomatoes. Trecho Farms reports that applied water use was reduced by as much as 50 percent from previous gravity/flood systems.

- At Hammond Ranch in Firebaugh, Fresno County, the owner established subsurface drip irrigation on 560 acres of cotton, tomatoes, and asparagus. Hammond Ranch reported improvements in yields and reduced water use. Cotton on drip requires 20 percent less water than the region's average (2.1 acre-feet of water per acre, instead of 2.7 acre-feet per acre) and has produced yields approximately 15 percent above the region's average. Yields on asparagus were 50 percent higher than those typical produced using furrow or sprinkler irrigation.

- Turlock Fruit Company, also in Firebaugh, started testing subsurface drip systems in the early 1990s on 300 acres of asparagus, 150 acres of melons, and 150 acres of cotton. The company reported that drip irrigation increased yields on these fields by 30 to 40 percent and reduced water use by 20 to 30 percent, as well as eliminating drainage problems. Soil salinity is monitored, and they have seen no increase in soil salinity on drip-irrigated fields.

- In the early 1990s, the California Energy Commission (CEC) granted low-interest loans to two California farmers to help cover the costs of converting bell pepper row crops to drip irrigation. In 1993, High Rise Farms near Gilroy installed buried drip irrigation equipment on forty acres, and Underwood Ranches near Oxnard installed buried drip irrigation on fifty acres. Technical assistance and monitoring were provided by the Irrigation Training and Research Center (ITRC) at Cal Poly San Luis Obispo. Both farms found that buried drip irrigation substantially increased pepper yields, decreased water consumption, and greatly improved profits. The average net revenue increase for High Rise Farms was $1,100 per acre per year; the average net revenue increase for Underwood Ranches was $1,900 per acre per year. Applied water use dropped between 16 and 25 percent at Underwood Ranches while yields went up between 10 and 50 percent. Applied water use at High Rise Farms dropped as much as 11 percent while yields went up as much as 56 percent. Initial installation and operation problems often experienced with new systems were successfully addressed and both farms subsequently expanded their drip irrigation systems with their own money. All these cases reported additional savings from reduced fertilizer and a pesticide application.

[1] These case studies come from M. Fidell, P.H. Gleick, A. Wong, 1998. "Converting to Drip Irrigation: Underwood Ranches and High Rise Farms," Sustainable Use of Water: California Success Stories. EDUCATION

Doctorate (PhD)	**University of California, Berkeley, Energy and Resources, 1986.**
Master of Science (MS)	**University of California, Berkeley, Energy and Resources, 1980.**
Bachelor of Science (BS)	**Yale University, in Engineering and Applied Science, 1978. Cum laude, with distinction.**

PROFESSIONAL EMPLOYMENT

Pacific Institute for Studies in Development, Environment, and Security.
Co-Founder and President. 1987-present

MacArthur Foundation Research and Writing Fellowship.
Fellowship in International Peace and Security. 1988-1990.

MacArthur Foundation Fellow in International Security.
Social Science Research Council/MacArthur Foundation. Post-doctoral position at the Energy and Resources Group, University of California, Berkeley. 1986-1988.

University of California, Berkeley.
Research Associate in the Energy and Resources Group. 1983-1986.

Office of the Governor of California.
Deputy Assistant for Energy and Environment. 1980-1982.

University of California and Lawrence Berkeley Laboratory.
Energy and Resources Group, Research and Teaching Associate. 1980-1981. Ecology Research Group Assistant, Energy and Environment Division. 1978-1980.

HONORS, AWARDS, FELLOWSHIPS

- Named MacArthur Fellow. October 2003
- Elected to Phi Beta Delta: Honor Society for scholarly achievement in international education. April 2003.
- Appointed to Water Science and Technology Board, National Academy of Sciences, Washington. June 2001.
- Named by the BBC as a "visionary on the environment" in its Essential Guide to the 21st Century.
- Elected Academician of the International Water Academy, Oslo, Norway. October 1999.
- MacArthur Foundation Research and Writing Fellowship. 1988-1990.
- Social Science Research Council-MacArthur Foundation Post-Doctoral Fellow in International Peace and Security Studies, June 1986 to June 1988.
- San Francisco Chronicle, one of "90 People to Watch in the '90s."
- *Cum laude*, Yale University 1978; *Distinction*, Engineering and Applied Science

PUBLIC AND PROFESSIONAL SERVICE (Current)

- Water Science and Technology Board, National Academy of Sciences, 2001-present.
- Public Advisory Committee: California Water Plan 2003. Department of Water Resources, 2001-present
- Board of Directors: Pacific Institute for Studies in Development, Environment, and Security, 1988-present.
- Editorial Board, Annual Reviews of Energy and the Environment, 2001-2006
- Editorial Board, Climatic Change, 1990-present.
- Editorial Board, Water Policy, 1997-present
- Advisory Council, International Water Academy, Oslo,Norway, 2003-2005.
- Scientific Advisor: IMAX Film "The Water Planet," 2003-present

PUBLIC AND PROFESSIONAL SERVICE (Past)

- Co-Chair: Water Sector: National Assessment of the Potential Impacts of Climatic Variability and Change on the United States, 1998-2000.
- Board of Directors: International Water Resources Association, 1997-2000.
- Global Environmental Change Committee, American Geophysical Union, 1993-1998.
- Public Advisory Forum: American Water Works Association, 1993-1998.
- 1990 Water Task Group, Second World Climate Conference, Geneva, Switzerland.
- Advisor, Comprehensive Freshwater Assessment, Stockholm Environment Institute, 1996-1997.
- Advisory Board: documentary film *Cadillac Desert* 1995-1997
- Advisory Committee: Climate Institute's Environmental Refugee Program, 1993-1995.
- Board of Directors: Environmental Science and Policy Institute, 1991-1997.
- Climate and Water Panel, American Association for the Advancement of Science, 1986-1990.
- Co-Chair, Working Group 2, Advisory Group on Greenhouse Gases (AGGG), WMO/UNEP, 1989-91.
- Committee on Science & International Security, American Association for the Advancement of Science, 1993-95.
- Editorial Board, Environment and Security, 1993-2001.
- Editorial Board, Encyclopedia of Life Support Systems, 1997-2002.
- Editorial Board, Encyclopedia of Global Change (Oxford University Press), 1996-2000.
- Editorial Board: Global Change and Human Health, 1999-2003
- Interim Board of Directors: Middle East Water Information Network, 1994-1996
- Project Steering Committee: IUCN (World Conservation Union): Water Demand Management in Southern Africa, 2000-2003.
- Scientific Review Group, President's Council on Sustainable Development, 1994-1996.
- Surface Water Committee, American Geophysical Union, 1992-1993.
- Working Group VIII Special Report, United States-Soviet Agreement on Protection of the Environment, 1989-90.

Arthur (Art) R. Jensen

Chief Executive Officer/General Manager
Bay Area Water Supply & Conservation Agency

1976: **Major Consulting firm in California – Principle Project Engineer**

Produced planning studies on San Francisco water system hydraulic upgrades, produced reports on water supply planning, wastewater outfall environmental impacts, reservoir yield analyses, wastewater and water system capital improvements.

1984: **San Francisco Water Department – Deputy General Manager and Acting General Manager**

Managed department response following the Loma Prieta earthquake. Initiated $104 million bond funded program for treatment and water system improvement. Provided analyses of water supplies and demand leading to water rationing and purchase of supplemental water supplies after the Hetch Hetchy water supply was impacted by drought and hydroelectric operations.

1990: **Contra Costa Water District: Assistant General Manager and Director of Planning**

Developed multi-agency agreement for water supply planning. Negotiated wastewater recycling agreement with local sanitation agency. Oversaw development of 10-year capital improvement program and subsequent updates. Managed development of water distribution plans, agency environmental documents and comments on environmental reports prepared by other entities.

1995-Current: **General Manager of the Bay Area Water Users Association (BAWUA), predecessor organization of the Bay Area Water Supply & Conservation Agency (BAWSCA)**

Currently Chief Executive Officer and General Manager of BAWSCA, comprising 27 cities, water districts and water companies that purchase water from the San Francisco Public Utilities Commission (SFPUC) for resale to their local service areas. The Agency represents its members' collective interests in their relationship with the SFPUC and on matters related to water conservation, water supply, facility reliability, operations, water quality and wholesale water rates. Manages development and implementation of regional water conservation programs. Worked on successful passage of the Wholesale Regional Water System Security Reliability Act.

Education: MS and Ph.D. in Environmental Engineering Science from California Institute of Technology.

BS in Engineering Physics from UC Berkeley.

Taught courses in water engineering and water resources management at both Stanford and UC Berkeley.

155 Bovet Road, Suite #302 San Mateo, CA 94402 Phone: 650-349-3000 Fax: 650-349-8395

BAWSCA

Bay Area Water Supply & Conservation Agency

July 17, 2008
Via e-mail and U.S.P.S

Mr. Bill Wycko
Acting Environmental Review Officer
San Francisco Planning Department
1650 Mission Street, Suite 400
San Francisco, CA 94103

Re: Analysis of New Variant to Water System Improvement Program Program Environmental Impact Report

Dear Mr. Wycko:

The Bay Area Water Supply & Conservation Agency (BAWSCA) represents the interests of 25 cities and water districts, an investor-owned utility, and Stanford University, who purchase water wholesale from the San Francisco Regional Water System. These agencies provide retail water service to 1.7 million people and over 30,000 businesses and community organizations in Santa Clara, San Mateo and Alameda counties.

The Limitation.
The San Francisco Public Utilities Commission (SFPUC) General Managers have sent two letters to the San Francisco Planning Department introducing the concept of using 2018 as an interim date for future water supply decisions in connection with the Program Environmental Impact Report (PEIR) and Water System Improvement Program (WSIP). The first letter was sent by Susan Leal on March 21 and the second was sent by Ed Harrington on May 2. The letters request that the Major Environmental Analysis (MEA) Division analyze a variant of the "No Purchase Request Alternative," examining the environmental impacts of limiting deliveries to the wholesale customers to 184 mgd through the year 2018.

The Demand.
This 184 mgd limitation is 10 mgd short of meeting the wholesale customers' projected 2018 demand of 194 mgd. The 194 mgd projected demand is based on the wholesale customers' extensive collaboration with the SFPUC which created reasonable and defensible demand projections of future water needs. In addition, the projected demand incorporates wholesale customer commitments to conservation, recycling and groundwater that will meet 19 percent of their total demands by 2030. However, if San Francisco honors its commitment to the 25 wholesale customers who have perpetual contracts and the customers' demand happens to be at least 184 mgd in 2018, then it is possible the SFPUC will, by necessity, choose to limit deliveries to the two interruptible wholesale customers, the cities of Santa Clara and San Jose.

Consequences of an Interruption of Supply.
If San Francisco interrupted or decreased supplies to these cities, the impacts would be severe. Families, businesses, hospitals and schools in San Jose and Santa Clara are dependent on the reliable high quality water that they have paid for year after year for almost 40 years. San Jose has 2332 customers with a residential population of 14,800 and 365 businesses of which 263 are industrial customers receiving this water. The portions of these cities served by the Regional Water System are isolated from the parts of the cities that are served by other water supplies.

Before the cities began purchasing water from the Regional Water System in the 1970's, both cities experienced over-draft of groundwater supplies and the resulting negative environmental impacts of land subsidence. San Francisco deliveries have been key to halting the over-drafting and associated subsidence and have allowed the Santa Clara Valley Water District to manage groundwater pumping. Despite these efforts, groundwater is not a sustainable substitution for water from the Regional Water System.

The Santa Clara Valley Water District, the primary water resources manager in Santa Clara County, states that any reduction in supplies to San Jose and Santa Clara would need to be addressed with an increase in development of and exportation of water from the already beleaguered Delta. Furthermore, additional infrastructure would be needed to treat and deliver the new supplies. The environmental impacts of the new water supply and infrastructure would be in addition to those already associated with the WSIP, could be significant, and have not yet been adequately analyzed as part of the WSIP PEIR.

The Cities are Maximizing Their Resources.
Both San Jose and Santa Clara have thriving recycled water programs and implement all the current Best Management Practices for water conservation. For example, in North San Jose, the area of that City that receives water from San Francisco, 13 percent of water needs are met with recycled water. This is projected to expand to 30 percent in the future, preserving high quality potable water for the most valuable uses, but will not eliminate the need for water from the Regional Water System. Santa Clara currently offsets 2.7 mgd of its needs with recycled water.

BAWSCA supports the idea of placing a realistic limit on increased deliveries from San Francisco's watersheds to the SFPUC service area until 2018 so that sustainable demand management and water supply alternatives can be examined and to the extent feasible, developed. BAWSCA opposes alternatives or variants that would ignore the needs of long-standing retail or wholesale customers of the system.

A Constructive Solution.
As noted by MEA in the draft PEIR, the impacts of increased diversions on the Lower Tuolumne River can be mitigated by investments in agricultural water conservation in the Tuolumne River basin. The MEA should evaluate the variant the SFPUC wants analyzed in conjunction with this mitigation measure. This approach could prevent an increase in net diversions from watersheds until the year 2018 while maintaining water deliveries to San Jose and Santa Clara. In our comments on the draft PEIR, BAWSCA proposed that the amount conserved should exceed the increase in diversions so the Lower Tuolumne River would experience a net increase in flow at times important to the endangered fish species present in that part of the river. As BAWSCA noted in its comments on the draft PEIR such a program should exclude land fallowing or other elements that might be detrimental to the farming community or cause third-party impacts.

This type of proposal has been supported by two environmental organizations. The Environmental Defense Fund has supported this specific proposal of investing in agricultural conservation, and the Pacific Institute has suggested that urban investment in agricultural conservation is a possible solution to future water management that should be explored.

Please ensure that the final PEIR fully examines and analyzes environmental and other consequences of cutting off deliveries to San Jose and Santa Clara as well as the opportunity to honor a limitation on net withdrawals from watersheds by implementing this mitigation measure.

Sincerely,

Arthur R. Jensen
Chief Executive Officer and General Manager

Re: Additional Information from City of San José as Part of WSIP PEIR Alternative Analysis

Dear Mr. Wycko:

The City of San José (City) is pleased to offer additional comments on the Program Environmental Impact Report (PEIR) for the San Francisco Public Utility Commission's (SFPUC) Water System Improvement Program (WSIP). San José previously commented on the PEIR (letter of September 27, 2007), generally supporting the PEIR as written and expressing support for the environmentally superior alternative (specifically, the Modified WSIP), which, along with the proposed program, includes the continued delivery of water from the San Francisco Regional Water System (RWS) to meet the projected water supply needs of San José. In addition, the City believes this alternative can be enhanced (as suggested by BAWSCA) to provide not only sufficient water supply for the projected water demand of all BAWSCA wholesale customers (including those for the Cities of San José and Santa Clara) but to also provide for greater flows in the lower Tuolumne River.

It has now come to our attention that the SFPUC has directed the San Francisco Planning Department to evaluate a variation of the "No Purchase Request Increase Alternative," a less desirable alternative, that may preclude a long-term assured supply of water to the City from the San Francisco RWS (letter of May 2, 2008, from Mr. Ed Harrington to SF Planning Dept).

Since 1969, the San José Municipal Water System has received water from the San Francisco RWS and distributed this water to customers in the North San José area. Under the current Master Water Sales Agreement, the cities of San José and Santa Clara receive water as "temporary and interruptible" customers. San José, with a population of nearly 990,000, is the largest city in the suburban service area, yet only accounted for 2.7% of the water purchased from SFPUC in 2006-07. The City desires to become a permanent customer of the SFPUC to ensure the continued delivery of water from the RWS to the North San José Area for the following reasons:

- The North San José area has no other viable alternative water supply available. San José firmly believes that continued delivery of this small amount of water supply to this area is the most environmentally responsible option for a long-term water supply to the North San José area.
- San José has a proven track record of aggressive water conservation and recycling to assure the most efficient use of water from the San Francisco RWS.
- There would be severe environmental and economic implications from San Francisco ceasing to provide water supply to San José.

San José has proven to be a cooperative customer and an asset to San Francisco and the Bay Area Water Supply and Conservation Agency (BAWSCA) in terms of supporting agency and state-wide water supply issues. Continuation of SFPUC supplies to North San José is the best and most environmentally responsible alternative for future water supply in this area.

No Viable Alternative Water Supply Available

San José relies on water from the San Francisco RWS to meet the water supply needs for the North San José area as no alternate potable water supply is available to accommodate normal deliveries. This area is hydraulically separate from the other water supplies that serve the City. Specifically, the Santa Clara Valley Water District has stated that it is not feasible for it to provide treated water to this area due to a lack of distribution system and treatment plant capacity. In addition, while this area does have access to local groundwater, this water supply is not a consistently dependable long-term source due to the known potential for groundwater overdraft and consequent land subsidence during times of increased use or drought. Prior to receiving water from the San Francisco RWS in the late 1960's, the North San José area was completely supplied by groundwater wells, resulting in land subsidence in the area.

San José Has a Proven Track Record of Aggressive Water Recycling and Conservation

San José has been implementing successful conservation and water recycling programs that have supported the efficient use of water from the San Francisco RWS since 1988 and 1998, respectively. San José and its tributary agencies have invested more than $250 million in a recycled water system. Recycled water has been supplied to North San José since 1998, and the system has continued to expand since that time. Recycled water is supplied to the area for a variety of uses, including irrigation, industrial processing, and dual plumbing. In 2006-07, recycled water accounted for approximately 13% of the water supplied to the North San José area. As of the end of 2007, recycled water has supplied a total of nearly 1.5 billion gallons to the North San José area. Ultimately, recycled water is projected to be used to meet almost 30% of the water demand in the North San José area, preserving high quality water from the San Francisco RWS for the highest value uses.

In 2006-2007, approximately 387,000 gallons per day of water savings was achieved in the greater San José/Santa Clara area through water conservation programs funded and implemented by the City. These programs include water use surveys, rebates for high efficiency clothes washers and toilets, and a comprehensive incentive program for commercial, industrial and institutional users to retrofit their facilities with water efficient technologies. As a signatory to the California Urban Water Conservation Council's Memorandum of Understanding for Urban Water Conservation, San José implements all fourteen of the conservation Best Management Practices.

Severe Economic and Environmental Implications from Curtailing This Water Supply

The delivery of water supply from the San Francisco RWS has been vital to the growth of the electronic industries in North San José and the entire Bay Area. In San José and Santa Clara, Hetch Hetchy water is provided mainly to industrial customers who rely on high purity water with low mineral content for their manufacturing. Without this pure water supply companies such as Cisco Systems, Cypress Semiconductor, Novellus Systems and others, would need to increase on-site treatment of water used for manufacturing, which in turn would increase operating costs. These industrial customers are essential to providing jobs and supporting the economic structure of the entire Bay Area region, not just San José. The manufacturing companies in this area continue to emphasize that it is essential to have water from the San Francisco RWS water as a reliable high quality source. The Santa Clara County Manufacturing Group in a letter to the City stated that "the high-tech electronics industry in Santa Clara County is heavily dependent on an adequate and predictable supply of water."

Obtaining water supplies from the SFPUC is the most environmentally responsible option for long-term water supply, as there is no other viable long term water supply to the North San José area at this time. A decision by San Francisco to curtail water supply to this area would require the identification and development of a new potable water supply as well as the design, construction, and implementation of a new water delivery system. As shown in San Francisco's draft Program EIR for the WSIP, obtaining water supplies from any other source would involve a greater cumulative environmental impact than would the continued delivery of water from the San Francisco RWS.

San José Supports the WSIP and Desires To Become A Permanent Customer

As a long term customer of the San Francisco RWS, the City has provided valuable support to the City of San Francisco and to the Bay Area in matters regarding state-wide water supply as well as state and national environmental issues. San Francisco and the greater Bay Area are facing several current and ongoing water supply challenges. Issues including climate change, the integrity of the Bay Delta and its habitat, implications of legal actions impacting Delta water supplies, seismic security, and upgrading of the San Francisco RWS all benefit from cooperative efforts, with water users throughout the Bay Area working together to provide a sufficient supply of quality water for the future. San José's support for these and other efforts will continue to be a great asset to the San Francisco.

The City desires to become a permanent customer of the SFPUC and to continue to pay for the benefits received from an assured water supply from the San Francisco RWS and for the environmental mitigation associated with the WSIP and the operations of the San Francisco RWS.

The City is concerned with maintaining the reliability and sustainability of its water supply and the water supplies of its neighboring cities. We have made investments and taken the steps available to us to ensure our ability to supply water to the residents and businesses in this portion of San José. We are concerned that the new alternative being examined by the San Francisco Planning Department at the direction of the SFPUC could result in significant environmental, operational and other impacts to the customers, businesses and residents. The City believes the PEIR will be inadequate unless it addresses these impacts satisfactorily.

In pursuing the environmentally superior alternative and ensuring that the San Francisco RWS is the long-term water supply source for the North San José area, San Francisco will be pursuing the best and most environmentally responsible approach towards the goal of providing a high quality, reliable water supply to the public.

If you have any questions regarding any of the information provided, please feel free to contact me at (408) 535-8560. We will contact your office in the first part of July to set up a meeting where the City can provide further details of the potential environmental and other impacts to the City and the region from the proposed variation of the "No Purchase Request Increase Alternative."

Sincerely,

John Stufflebean, Director
Director, Environmental Services

Re: Additional Information as Part of WSIP PEIR Alternatives Analysis

Dear Mr. Wycko:

The City of Santa Clara is pleased to offer additional comments on the draft Water System Improvement Program (WSIP) Program Environmental Impact Report (PEIR). Specifically, this letter provides additional detail as to the potential environmental and economic impacts that would result from a decision by San Francisco to interrupt the delivery of water supply to the City of Santa Clara. As part of your analysis of alternatives that consider the restriction of water sales to San Francisco's existing wholesale customers, we believe that specific information is a critical element that must be addressed as part of the impact analysis for any such alternative.

The City of Santa Clara provided comments in a letter dated August 23, 2007 that included supporting the draft PEIR. The City of Santa Clara also supported the "Modified WSIP/Environmentally Superior Alternative" that was presented in the draft PEIR. In addition, the City believes this alternative could be enhanced (as suggested by BAWSCA) to provide not only sufficient water supply for the projected water demand of all BAWSCA wholesale customers including those for the Cities of Santa Clara and San Jose while still providing for greater flows in the (lower) Tuolumne River.

In our earlier letter dated August 23, 2007, we emphasized the need to proceed with the WSIP for regional water supply reliability. The San Francisco Public Utility Commission's (SFPUC) proposed program included treating the City of Santa Clara as a full partner in this endeavor along with all other BAWSCA agencies. We have been a steady wholesale customer from the San Francisco Regional Water Supply (RWS) since 1974 and we understand that the SFPUC has directed the San Francisco Planning Department to evaluate a variation of the "No Purchase Request Increase Alternative", a less desirable alternative, that may preclude a long-

1500 Warburton Avenue

term assured supply of water to the City of Santa Clara from the San Francisco Regional Water Supply (RWS) (letter of May 2, 2008 from Mr. Ed Harrington to SF Planning Dept).

The City of Santa Clara is committed to the efficient use and sustainability of all of our regional water supplies. The City has demonstrated this commitment through the implementation of extensive water conservation, use of recycled water, and smart growth development. However, we are concerned that San Francisco may take unilateral action that would preclude providing the City of Santa Clara an assured long-term supply of water from the San Francisco RWS. In particular we would like to detail specific undesirable consequences that could or would occur as result of any termination or interruption of that supply.

1. Under our current contract this water supply is distributed within that part of Santa Clara north of US 101 (Bayshore Freeway). This service area is to a considerable degree hydraulically isolated from the rest of the City's water system. While San Francisco RWS water comprises about 17% of the whole City's water supply, it represents nearly 90% of the drinking water in the northerly portion of the City on an average day.

2. The City does not have good alternative treated water supply sources. Although the City has the ability to pump groundwater to help offset an interruption of San Francisco RWS supply, and has constructed two new wells in the north of US 101 service area to help improve our water system reliability, one of these wells require additional treatment to remove naturally occurring constituents in the groundwater.

3. Ultimately any attempt to offset the loss of San Francisco RWS supply would impact the regional groundwater supply of Santa Clara Valley. The groundwater basin is managed by the Santa Clara Valley Water District. They have provided separate comments on the PEIR. The District's (Mr. Whitman) letter to you, dated September 26, 2007, includes the following: "We urge San Francisco to adopt the proposed... WSIP and meet all the program goals and objectives. ***Any diminution in levels of service provided by SFPUC could result in significant impacts to water resources in Santa Clara County with associated environmental and socio-economic consequences.***" [emphasis added]. Mr. Whitman's letter dated June 24, 2008 also identifies certain impacts of over-pumping the groundwater basin. The greatest detrimental effect of excessive extraction of groundwater is land subsidence with the accompanying affects of collapse of existing water wells and the loss of flood flow carrying capacity of all creeks and rivers with levees. Santa Clara Valley has a history of land subsidence from over-drafting this valuable aquifer. Past land subsidence has also reduced the water storage capacity of the regional aquifers.

4. While not directly served by District's imported treated water, it could be possible to offset some of the loss of San Francisco RWS supply in the northerly portion of the City of Santa Clara by an increase in supply from the District's treated water. As was stated in Mr. Whitman's letters, this in turn would increase reliance on water supplies from the State Water Project and Central Valley Project; both sources are faced with restrictions on pumping from the Delta.

5. Although the City has 9.4 million gallons of storage located in the northerly service area, this storage is adjacent to and replenished by San Francisco RWS water supply. Any long-term interruption of San Francisco RWS supply would reduce our over-all system reliability for emergencies and peak demands.

6. Many Silicon Valley technology companies corporate headquarters are among the City's retail water customers in this northerly service area. Many of these use de-mineralized water in their manufacturing processes, and have come to depend on the low mineral content and high quality of San Francisco RWS water. Any interruption of this high-quality supply will force these industries to expend more energy treating the water they need and will increase their overall water demand due to reduced recovery ratios. The additional reject water and blow-down from cooling towers will also increase the flows to the regional wastewater treatment plant. Based on our experience of the past few interruptions of water supply from the San Francisco RWS, water demand increases from 10% to 20% when using groundwater and sanitary sewers increases up to 200%. This increase to sanitary sewer discharge will increase energy use at the wastewater treatment plant. Both results will increase the carbon footprint for these industries.

7. The resulting impact of higher operating costs as outlined in item 6, could suppress job creation within the City of Santa Clara and the region due to large companies relocating part of their business or smaller companies relocating altogether.

Even though over the last 20 years the City's populations has increased by 25%, the residential water demand has stayed relatively flat or decreased due to our local and regional water conservation programs, changes in the plumbing code and the use of recycled water. As was mentioned in our letter of August 23, 2007, the City of Santa Clara has managed to provide for all of the increased water demand for the past two decades in the North of Bayshore area by expanding our recycled water delivery system to serve irrigation, dual-plumbed buildings and industrial customers.

The City of Santa Clara is concerned with maintaining the reliability and sustainability of its water supply and the water supplies of its neighboring cities. We have made investments and taken the steps available to us to ensure our ability to supply water to the residents and

The City of Santa Clara desires to become a permanent customer of the SFPUC and to continue to pay for the benefits received from an assured water supply from the San Francisco RWS. We remain concerned about the known risks of failure of the San Francisco RWS following a major seismic event and therefore continue to urge the SFPUC to proceed with the implementation of the Environmentally Superior Alternative for the WSIP as expeditiously as possible.

If you have any questions regarding the information in these comments, please feel free to contact me at (408) 615-2010. We will contact your office in the next week to set up a meeting where the City of Santa Clara can provide further details of the potential impacts to the City of Santa Clara from the proposed variation of the "No Purchase Request Increase Alternative."

Sincerely,

Alan Kurotori

Re: March 21, 2008 and May 2, 2008 Letters Regarding Analysis of Variant to WSIP PEIR

Dear Mr. Wycko and Mr. Harrington:

I am writing to express our concerns regarding San Francisco Public Utilities Commission's (SFPUC) request to consider a variant to the proposed program in the final PEIR. Our specific concerns relate to SFPUC's desire to cap its water delivery service to the wholesale customers at 184 mgd until 2018 and uncertain amount of supply delivery beyond 2018.

As described in my September 26, 2007 comment letter on the draft PEIR (see attached), Santa Clara Valley Water District (District) is the primary water resources manager for Santa Clara County. SFPUC and the District share the responsibility of providing a clean, safe and reliable water supply to cities and entities in the northern portion of Santa Clara County. SFPUC supplies constitute 100% of some of these cities' water supply in those areas and there is very little or no alternative supply from the District or elsewhere.

In particular, we are very concerned with implications and potential consequences of the 184 mgd delivery cap on the cities of San Jose and Santa Clara since they both hold "interruptible" contracts with San Francisco. If SFPUC supplies to these two cities are not included in the 184 mgd cap or their future deliveries are dramatically diminished from their current and historical purchases, it will create immense impacts to health and safety of the communities, water and environmental resources in Santa Clara County, as well as economic viability of the region.

San Jose and Santa Clara are the historical "epicenters" of land subsidence due to overdraft of groundwater. If SFPUC supplies to the two cities are cut-off or reduced, the cities will have to use more groundwater as replacement since there is insufficient capacity in both the District's and the cities' treated water systems. This potential increase in groundwater extraction could lead to re-initiation of land subsidence and erase decades of conjunctive use management efforts undertaken by the District.

Furthermore, reduced SFPUC supplies to Santa Clara County could create a ripple effect to water and environmental resources in the Delta. More than half of the average year supplies in Santa Clara County is imported by the District from the Delta. Any reduction in SFPUC supplies would need to be mitigated with additional supply development and could lead to increased reliance on exportation of water from the Delta.

We are extremely concerned with the adequacy of analysis, disclosure, documentation and mitigation for this proposed variant to the WSIP PEIR, especially because it was proposed after the release of the draft PEIR and it was not widely publicized. The District welcomes any opportunity to work with San Francisco to understand the implications and impacts from this variant and to develop acceptable mitigation measures if it were to be incorporated into the final program alternative.

Sincerely,

Keith Whitman
Deputy Operating Officer
Water Supply Management Division

September 26, 2007

Mr. Paul Maltzer
Environmental Review Officer
Water System Improvement Program PEIR
San Francisco Planning Department
1650 Mission Street, Suite 400
San Francisco, CA 94103

Subject: Comments on the Draft PEIR

Dear Mr. Maltzer:

The Santa Clara Valley Water District (District) provides wholesale drinking water supply for 1.7 million residents and is the primary water resources manager for Santa Clara County. We manage the conjunctive use of surface and groundwater resources to ensure that water supply is reliable to meet current and future demands. We actively manage the groundwater basin to optimize beneficial uses and aggressively protect the groundwater basin from contamination and minimize inelastic land surface subsidence.

As you well know, San Francisco Public Utilities Commission (SFPUC) and the District share the responsibility of providing a clean, safe and reliable water supply to cities and entities in the northern portion of Santa Clara County. SFPUC supply comprises 15% of the overall water supply in Santa Clara County and constitutes 100% of the water supply to some cities.

We expect SFPUC to continue providing its water supply in Santa Clara County and meet the projected 2030 purchase requests submitted by the wholesale customers. This expectation is described and documented in the District's and the cities' 2005 Urban Water Management Plans. The cities collaborated with SFPUC on its demand projection and water use efficiency studies and arrived at reasonable and defensible projections on future water needs. These water supply and demand projections constitute the foundation of water resources planning for the next 30 years, for the cities, SFPUC and the District.

We urge San Francisco to adopt the proposed Water System Improvement Program (WSIP) and meet all the program goals and objectives. Any diminution in levels of service provided by SFPUC could result in significant impacts to water resources in Santa Clara County with associated environmental and socio-economic consequences.

Santa Clara Valley had a legacy of land subsidence in the 1920's and 1930's due to over-extraction of ground water. Through the District's water importation and conjunctive use management, land subsidence was halted by the late 1960's and the District has been vigilant in preventing its re-occurrence. Understandably, we are very concerned with any potential re-directed impacts on our groundwater basin and local or imported surface water resources due to SFPUC's reduction in supplies or level of service provided to Santa Clara County. We also urge San Francisco to fully address any potential impacts on water supplies for the State Water Project and Central Valley Project users.

We support SFPUC's goal to maximize water conservation, recycling and desalination. The District has been very aggressive in implementing programs to maximize water use efficiency and further diversify our sources of supply. We believe these program areas are ideal for SFPUC and the District to partner with local land-use entities in their implementation. However, there are practical limits in "implementability" of these programs and they cannot be used as "stand-alone" substitute alternatives or variants because they fail to meet the overall program goals.

We look forward to San Francisco addressing our concerns adequately and adopting the PEIR and WSIP expediently so that the critical work of securing the water supply for the Bay Area communities can begin.

Sincerely,

Keith Whitman

Keith Whitman
Deputy Operating Officer
Water Supply Management Division

RECEIVED

MAR 0 4 2008

CITY & COUNTY OF S.F.
PLANNING DEPARTMENT
M E A

February 22, 2008

Paul Maltzer, Environmental Review Officer
San Francisco Planning Department
1650 Mission Street, Suite 400
San Fransisco, CA 94103

Dear Mr. Maltzer,

Your environmental review of the San Francisco Public Utilities Commission's plan to take more water from the Tuolumne River fails to adequately identify and address all of the environmental impacts to the River. I urge you to undertake additional studies before finalizing this document. I also urge you to view the water from the Tuolumne, as water being taken from the entire watershed, thus reducing the health of the Tuolumne itself, the San Juaquin and the San Francisco Bay Delta.

I support the alternatives identified in draft document that protect the Tuolumne River from new diversions. Requiring more water conservation, efficiency, and recycling is the best way to lessen impacts on the Tuolumne River while promoting a sustainable water plan for the Bay Area.

Only by ensuring that healthy amounts of water continue to flow into the Tuolumne River can we protect this irreplaceable treasure.

Sincerely,

Emily McGinty
24000 Casa Loma Road
Groveland, CA 95321

N. Technical Memorandum – Estimation of Flow Changes in Lower Alameda Creek with Implementation of the WSIP

APPENDIX N

Technical Memorandum – Estimation of Flow Changes in Lower Alameda Creek with Implementation of the WSIP

Introduction

To determine the effects of the WSIP, flow changes in lower Alameda Creek at the Niles Gage were estimated using the following methodology:

1. Available U.S. Geological Survey (USGS) gage records were reviewed on a monthly basis for upper Alameda Creek (Alameda C BL Welch C), Arroyo de la Laguna (Arroyo de la Laguna A Verona), and lower Alameda Creek (Alameda C Near Niles) for overlapping periods of gage record (Water Years [WY] 2000 to 2007).

2. Monthly relationships were developed between the three gages to determine flow proportions at the Niles Gage from each of the two major upstream watersheds, named Arroyo de la Laguna (ADLL) and upper Alameda Creek for this analysis to reflect the major tributaries draining each watershed.

3. Gage records from Arroyo Hondo (unimpaired inflow to Calaveras) were used to classify the years of available gage record into year types based on the index developed for the PEIR analysis. The PEIR analysis used aggregated annual inflow to local reservoirs to rank years for the 82-year period (from 1921 to 2002) into 20th percentiles. The five percentile groups were labeled: Wet, Above Normal, Normal, Below Normal, and Dry.

4. Analysis of the eight years of gage record was performed using the flow changes developed for the PEIR as input to the Hetch Hetchy/Local Simulation Model (HH/LSM). The analysis was performed based on hydrologic year types. Charts and tables tabulating the expected changes in flow for each of the eight actual years were developed to illustrate the potential effects of the WSIP on flow in lower Alameda Creek for the period of available gage record.

Analysis

Gage Record Analysis

Flow records were reviewed on an average monthly flow basis at three USGS gages in the Alameda Creek watershed for periods of overlapping record (WY 2000-2007). The three gages were chosen to represent flow in the two major upstream basins of the Alameda Creek watershed (upper Alameda Creek and Arroyo de la Laguna) and flow in the lower reach of Alameda Creek. Upper Alameda Creek flow is recorded by the USGS “Alameda C BL Welch C” gage (AC Welch Gage), located in the Sunol Valley reach of Alameda Creek below the confluence at Welch Creek, near the Sunol Valley Water Treatment Plant. Arroyo de la Laguna flow is monitored by the USGS “Arroyo de la Laguna A Verona” gage (ADLL Gage) on ADLL approximately three miles upstream of the ADLL and Alameda Creek confluence. The USGS “Alameda C Near Niles” gage (AC Niles Gage) records a combination of these two flows as well as the contribution or loss of flow from the watershed between these gages and the Niles Gage, including flow from San Antonio Creek and State Water Project releases.

Figure N.1 shows the location of the three gages and the watersheds associated with each gage.

Figure N.2 presents the mean monthly flow over the eight-year period for the three gages. Review of the data reveals that flow measured at the ADLL Gage (shown as a blue shaded area) generally contributes a higher percentage of the flow measured at the Niles Gage (shown as a black line) compared to that measured at the Welch Gage (shown as a green shaded area). The discrepancy between the summation of the ADLL and AC Welch flows and the flow at the Niles Gage (the white space below the black line) is assumed to be other inflow from the watershed between the two upper gages and the Niles Gage (labeled Niles-SA watershed on Figure N.1). The Niles-SA watershed includes releases made from San Antonio Reservoir and the State Water Project, which occur downstream of the two upper gages.

Releases or spills from San Antonio Reservoir rarely occur. The flow in San Antonio Creek is usually the result of groundwater seepage or runoff from the watershed downstream of Turner Dam. The Niles-SA watershed contribution noted during the summer months is assumed to be primarily releases from the State Water Project and contribution from groundwater in Niles Canyon. Also notable in the chart are the spikes in flow from upper Alameda Creek in the winter and spring of WY 2005 and 2006. These spikes are the result of above-normal runoff in the watershed as well as restricted storage at Calaveras Reservoir.

Niles-SA watershed values, as mentioned previously, were calculated by subtracting ADLL and AC Welch flow rates from the flow gaged at Niles. Negative values for the Niles-SA watershed are assumed to be the result of loss to groundwater (particularly in the Sunol reach downstream of the Welch Gage), discrepancy introduced when converting daily flows to monthly average flows, or gage error.

Table N.2 provides a summary of the month-by-month analysis for WY 2000-2007.

TABLE N.2
MEAN MONTHLY PERCENTAGES OF WATERSHED CONTRIBUTIONS
AT THE AC NILES GAGE, WY 2000-2007

	OCT	NOV	DEC	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP	WY Total
ADLL	58%	81%	71%	61%	70%	46%	42%	34%	40%	47%	41%	43%	55%
AC Welch	6%	3%	23%	40%	24%	44%	45%	59%	39%	3%	1%	1%	33%
Niles-SA	36%	16%	6%	-1%	5%	10%	13%	7%	20%	50%	58%	57%	13%

Table N.3 shows the relative contribution of the upstream watersheds to flow at the Niles Gage over the past eight hydrologic years from WY 2000 to 2007. SFPUC operations would alter flow in the upper Alameda Creek watershed. Therefore, implementation of the WSIP would only affect approximately one-third of the flow that contributes to flow at the Niles Gage.

TABLE N.3
SUMMARY OF FLOW CONTRIBUTIONS AT THE AC NILES GAGE, WY 2000-2007

Watershed	Eight-Year Average Contribution	Eight-Year Range of Contribution
Arroyo de la Laguna	55%	43% – 71%
Upper Alameda Creek	33%	5% – 46%
Niles–San Antonio Creek	13%	8% – 27%

Classification of Year Types

The ranking system for the local watershed systems used for the PEIR (5 Reservoir Index) was developed for WY 1921 to 2002. Years were ranked into 20th percentiles and labeled Wet, Above Normal, Normal, Below Normal, and Dry based on inflow to local (non-Tuolumne) reservoirs. The ranking system developed for the PEIR covers WY 2000 to 2002. WY 2003 to 2007 were ranked according to the same index using unimpaired runoff at Arroyo Hondo. **Table N.4** summarizes the year types over the period analyzed.

TABLE N.4
YEAR TYPES FOR WY 2000-2007

2000	Above Normal
2001	Below Normal
2002	Below Normal
2003	Normal
2004	Normal
2005	Above Normal
2006	Above Normal
2007	Dry

Table N.4 shows that the past eight years provide a reasonable cross-section of water year types, with only wet years being absent.

Table N.5 presents a series of tables summarizing the monthly flow reductions predicted by the HH/LSM for Alameda Creek below the San Antonio Creek confluence. The first of the Table N.5 tables shows the existing condition (Calaveras Down) compared with the WSIP. The second table compares the Calaveras Up scenario (i.e., the pre-DSOD restricted condition at Calaveras Reservoir) with conditions under the WSIP. Note that the biggest impacts on flow in Alameda Creek with the WSIP would occur in Normal and Above Normal months, which are both represented in this analysis.

Increase of greater than 1%
Decrease of greater than 1%
Decrease of greater than 5%

The Base condition with Calaveras Up was included in the analysis because the DSOD restriction on Calaveras Reservoir was implemented in 2001. Review of Calaveras Reservoir water surface elevations reveals that the restricted operations were fully implemented in WY 2002. Therefore, this analysis uses the Base, Calaveras Up condition for WY 2000-2001 and the Base, Calaveras Down condition for the remainder of the years.

Revised model runs (April 2008) for the Base (Calaveras Down) and the WSIP were used for WY 2002-2007. Model runs performed in July 2006 for the Draft PEIR were used for Base (Calaveras Up) and the WSIP for WY 2000-2001. Model runs for the Base (Calaveras Up) scenario were not revised in 2008; therefore, the earlier model runs were used for the Calaveras Up condition in the first two years of the analysis.

The implementation of the WSIP assumes that there would be releases from either Calaveras Dam or the Alameda Creek Diversion Dam in accordance with the 1997 California Department of Fish and Game Memorandum of Understanding (MOU) as well as recapture of those flows upstream of the confluence with San Antonio Creek. Therefore, the flow in Alameda Creek below San Antonio Creek calculated for the WSIP does not include these MOU flows; the model assumes they have been recaptured and conveyed to the regional water system. The model does not account for groundwater loss in the Sunol Valley. Therefore, both the base case and the future scenario with implementation of the WSIP assume no change in groundwater losses.

This assumption is conservative for two reasons. First, the future condition will likely include the cumulative project to install slurry walls adjacent to the quarries in the Sunol Valley, reducing the loss to groundwater and increasing the amount of flow that reaches lower Alameda Creek from the Sunol Valley. Secondly, this analysis likely overestimates the contribution of upper Alameda Creek to flow at the AC Niles Gage, because no loss to groundwater is assumed in the Sunol reach of Alameda Creek below the AC Welch Gage. If groundwater losses were included in the model, the upper Alameda Creek watershed contribution would be reduced and the Niles-SA watershed contribution would be increased.

Analysis of the Eight Water Years of Record

The percent reductions in monthly flow estimated using the HH/LSM and presented above were applied to monthly gage flow at AC Welch. The resulting changes in flow at AC Welch and AC Niles are presented in the following charts and tables. Appendix N1 presents a year-by-year summary of monthly flow changes at AC Welch and AC Niles that would occur with the WSIP.

The AC Welch Gage and the HH/LSM analysis location of Alameda Creek below the San Antonio confluence are not the same. The San Antonio Creek confluence is approximately 2.7 miles downstream of the AC Welch Gage. This analysis applied the percent change in flow from the HH/LSM analysis, not actual flow numbers, to the Welch Gage. This difference in location was not considered significant for this level of analysis, and the percent reduction in flow was considered applicable for flow in Alameda Creek in the vicinity of the Welch Gage.

Table N.6 presents the results of applying the HH/LSM flow reductions to the gage record for AC Welch for WY 2000-2007. The second table represents the future condition with implementation of the WSIP.

Decrease of greater than 5%

Figure N.3 and **Table N.7** detail the predicted changes in flow that would occur in Alameda Creek at AC Niles over the eight-year period (WY 2000-2007) with implementation of the WSIP. On the chart, the solid blue area represents average monthly gage flow at AC Niles, and the black line is calculated flow under the WSIP. The discrepancy between the two lines represents the change between gage records and calculated flow under the proposed program.

The analysis shows that reductions in flow at the Niles Gage would occur with the WSIP when compared to the current DSOD-restricted operating condition, based on the historical hydrology from 2001 to 2007. Reductions of up to 18% in average monthly flow could occur in years similar to the past eight years of record. The maximum flow reduction would occur during January of 2005, an Above Normal year. However, there would be a flow increase of 13% in April of that same year type. No changes in flow would occur in Dry and Below Normal years, with the exception of a slight decrease in February of Below Normal years. It should be noted that in 2000, an Above Normal year, there would be up to a 20% increase in flow with implementation of the WSIP; this year represents historical operating conditions prior to the DSOD operating restrictions.

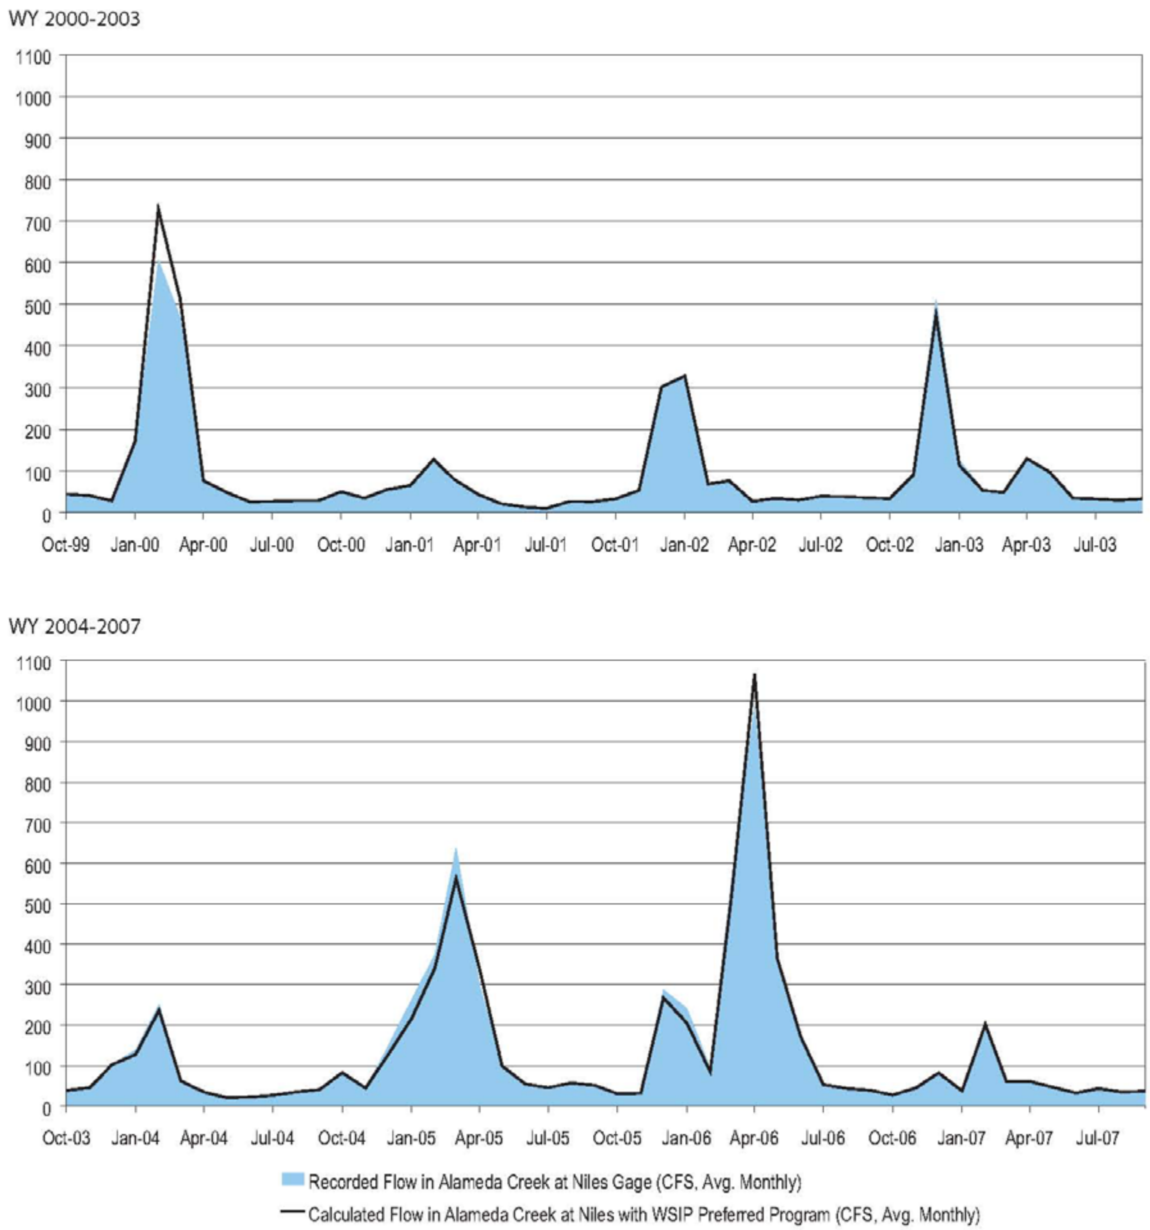
The past eight years include four of the five year types; note that a Wet year is absent. However, as shown in Table N.5, the largest reductions in flow with the WSIP would occur during Normal and Above Normal years, which are included in this analysis. Therefore, this analysis covers the flow reduction scenario with the greatest impacts expected under the WSIP.

The largest decrease in flow in lower Alameda Creek in the analysis would occur in a month similar to January of 2005, with a reduction in average monthly flow of 46 cubic feet per second, or 18%, of the average monthly flow recorded in January 2005. This corresponds to a reduction in upper Alameda Creek of 43%. Further review of the data reveals that flow reductions are calculated to occur in December through March of Normal to Wet years and in April of Wet years. In all other months, including winter months of Below Normal (with the exception of a slight decrease in February) and Dry years, flow in upper Alameda Creek and at Niles would either remain the same or increase under the WSIP.

Limitations of the Analytical Results

- The data are based on monthly flows and do not reflect the range of fluctuations that occur during shorter time intervals. However, the monthly data provide a sufficient level of detail to determine the general magnitude of the effects on flow in lower Alameda Creek, as well as the season and water year type in which the effects would occur. The monthly data also provide a definitive indication of when no changes would occur.

- The discrepancy between the model prediction for flow in Alameda Creek below the San Antonio Creek confluence and the application of these flow reductions to the AC Welch Gage may introduce some error. The model flow predictions include the flow contribution from the watershed between Welch Creek and the San Antonio Creek confluence, and the flow contribution from San Antonio Reservoir releases. However, releases from the reservoir are very infrequent, and the contribution from the watershed between Welch and San Antonio Creeks is minor.



Notes:
- WSIP conditions includes recapture of MOU flows released from Calaveras Dam.
- Years 2000 and 2001 analysis includes a comparison of Base with Calaveras Up vs WSIP Proposed Program. DSOD restriction was implemented in 2001, with Calaveras Reservoir level reduction beginning in WY 2002.
- Analysis for WSIP only, no other cumulative projects analyzed.

Increase of greater than 1%
Decrease of greater than 1%
Decrease of greater than 5%

- As discussed previously, this analysis did not account for losses to groundwater in the Sunol Valley. Losses to groundwater can be significant, and inclusion of this assumption in the analysis would decrease the upper Alameda Creek contribution to flow at the AC Niles Gage and would mute the impacts of the WSIP, particularly if the future condition assumes less loss to groundwater with implementation of the slurry wall project adjacent to the Sunol Quarries. The current analysis is therefore conservative; however, including a quantified loss to groundwater in the Sunol reach was considered too speculative.

- A Wet year is not included in the analysis because one was not present in the available gage record. A Wet year could be synthesized; however, since the greatest effects of the WSIP are shown to occur in Above Normal and Normal years, the current analysis includes the year types with the greatest impact on flows.

- Actual upstream operations in the upper Alameda Creek and ADLL watersheds were not accounted for in the analysis. For instance, large spikes in flow in 2005 and 2006 are likely a result of DSOD-restricted operations as well as releases made from Calaveras Reservoir for the flow/infiltration studies in the Sunol Valley. The additional releases for these studies had the affect of increasing upper Alameda Creek's flow contribution at the Niles Gage. Similar operational anomalies could be reviewed for the ADLL watershed and used to refine the flow percentages from the upper watersheds, but such an effort exceeded the scope of this analysis.

Hydrologic Modeling – Additional Supporting Information

O1 – Updated HH/LSM Assumptions and Results—Proposed WSIP

O2 – Updated HH/LSM Assumptions and Results—Modified WSIP Alt.

O3 – Updated HH/LSM Assumptions and Results—Phased WSIP Variant

O4 – Analysis of WSIP upon the San Joaquin River and the Sacramento-San Joaquin Delta

APPENDIX O1

Memorandum

Subject: **Updated HH/LSM Assumptions and Results – Proposed WSIP**

From: **Daniel B. Steiner**

Date: **March 20, 2008**

1. Introduction

This memorandum summarizes assumptions for, and discusses the interpretation of, the Hetch Hetchy/Local Simulation Model (HH/LSM) results for the simulation of the Water System Improvement Program (WSIP or the proposed program). Table 1-1 and Table 1-2 summarize the program/setting characteristics and modeling assumptions, and the performance and hydrologic results, respectively, for the WSIP as they compare to the modeled existing setting (2005, with Calaveras Reservoir constrained by the California Division of Safety of Dams [DSOD] restrictions).

The hydrology under the proposed program is primarily discussed in terms of a comparison to the baseline condition presented in the Draft Program Environmental Impact Report, i.e., the simulated current (2005) operation of the San Francisco Public Utilities Commission (SFPUC) regional water system, assuming that the operation of Calaveras and Crystal Springs Reservoirs is constrained by DSOD restrictions. Primary hydrologic parameters such as projected water deliveries, reservoir storage, and stream flows are compared, and additional parameters that assist in identifying the causes of hydrologic changes are also described as needed.

APPENDIX O1

APPENDIX O1

Notes for Table 1-1 and Table 1-2

1. Baseline condition represents the existing conditions at the time of Notice of Preparation publication in September 2006. This is the baseline used to assess WSIP program impacts and impact significance. This setting is indicative of DSOD restrictions on Calaveras and Crystal Springs Reservoirs.

2. N/A

3. N/A

4. The time horizon for the setting of the scenario. The baseline condition scenario is depicted for recent conditions, while the proposed WSIP, variants, and alternatives are depicted for the future at full buildout and implementation (i.e., conditions in the year 2030).

5. HH/LSM simulation study name.

6. The customer purchase request (demand) information is based on the demand and request studies prepared by the SFPUC in coordination with the wholesale customers. This demand on the regional water system includes both the SFPUC retail customers and wholesale customers. The current (2005) average annual demand is 265 mgd and the projected 2030 average annual demand is 300 mgd, assuming the SFPUC adopts the updated wholesale customer purchase requests as part of renewing the Master Sales Agreement with these customers (due in 2009).

7. Certain scenarios include development of additional water supply from a combination of recycled water projects, groundwater projects, and conservation, utilized every year and not subject to reduction during drought.

8. The average annual demand for supplies from the combination of SFPUC local watershed, Tuolumne River, and programs not included in the regional water conservation, recycling, and groundwater programs shown.

9. Modeled results for SFPUC deliveries, with supplies added for regional water conservation, recycling, and groundwater programs. Total deliveries and supply will be less than full customer purchase requests due to rationing in some years.

10. Shows only the features that affect hydrologic results of the system operation simulations. Additional projects are included in the WSIP.

11. Illustrates the frequency and severity of water supply action or the severity of systemwide rationing. Only years when a variable water supply component is implemented or rationing occurs are shown. "DD" illustrates the shortage results for years included in the prospective drought period of the SFPUC design drought. These years contribute to establishing system operation protocols but are not included in the hydrologic assessment analyses.

12. Rationing policy cap: The SFPUC WSIP level of service goal is to maintain rationing on the regional system at no more than 20% during any one year of the drought. Some alternatives do not achieve this level of service goal. Performance is indicated for the Design Drought ("DD") sequence and for the "Historical" hydrologic sequence.

13. Water supply elements develop water in different amounts from year-to-year, and in some instances only develop water during dry years. This information is provided to illustrate a comparison between local watershed supplies, Tuolumne River supplies, and other identifiable water supplies used to meet system purchase requests. Values are stated in units of average annual quantities during the simulated historical sequence.

14. Results from HH/LSM analysis of each scenario. Values represent the average annual production of each element of supply during the design drought period.

15. Simplified calculation of system deliveries during the SFPUC design drought. The value represents the application of systemwide shortages to the demand level being met with SFPUC local watershed, Tuolumne River, and other developed supplies, and does not include supplies from regional water conservation, recycled water, or groundwater projects. Average value may be slightly misstated (up to 3 mgd) due to metric of analysis that does not account for differences in residual storage between studies. "Nominal" Firm Yield represents the yield of each scenario after adjustment for minor residual storage differences.

16. Supplemental releases from Calaveras Reservoir for fisheries (1997 CDFG MOU) of up to 6,300 acre-feet per year and the Alameda Creek recapture facility project are tied to implementation of the Calaveras Dam Replacement project (SV-2). When the dam is replaced and capacity restored, the flow release and recapture will both occur. The release requirement is based on supplementing other occurring flows below Calaveras Reservoir, sometimes not requiring the full 6,300 acre-feet.

17. SFPUC actions are assumed to not change MID/TID diversions so as to isolate and possibly overstate the WSIP's effects on the Tuolumne River below La Grange Dam. The Districts' diversions are assumed to be constant among the scenarios to provide comparable results of WSIP-alone effects. The exception is for the Modified WSIP Alternative, in which the MID/TID diversion is reduced by the amount of SFPUC transfer.

18. Participation in the San Joaquin River Agreement is assumed. Although the agreement expires after 2010, it is assumed that a subsequent similar agreement or requirement of the Districts will occur. HH/LSM does not explicitly model the Districts' participation in the agreement; however, their participation if modeled would result in only minor differences in results and would not change impact conclusions.

19. From HH/LSM results for modeling the SFPUC design drought period.

20. From HH/LSM results for modeling the system operations for the historical hydrologic period 1921-2002. Values indicate average annual quantities during simulated historical period.

2. Proposed WSIP

The SFPUC proposes to adopt and implement the WSIP to increase the reliability of the regional water system. The WSIP is a program to implement the service goals and system performance objectives established by the SFPUC for the regional water system in the areas of water quality, seismic reliability, delivery reliability, and water supply through the year 2030.

The WSIP level of service objectives for water supply are to: (1) fully meet customer purchase requests in nondrought years through planning year 2030, estimated at 300 million gallons per day (mgd) average annual delivery; and (2) provide drought-year delivery with a maximum systemwide delivery reduction (rationing) of 20 percent in any one year of a drought. These objectives correspond to a required system firm yield of 256 mgd in 2030. System firm yield is defined as the average annual water delivery that can be sustained throughout an extended drought. The current firm yield of the system is 219 mgd under the current restricted operating conditions that limit storage levels in Calaveras and Crystal Springs Reservoirs.

During nondrought years, the SFPUC would serve the increased 35 mgd in purchase requests through a combination of conservation, water recycling, groundwater supply programs, increased diversions from the Tuolumne River, and greater utilization of Bay Area watershed supplies associated with the restoration of operational storage capacity (primarily in Calaveras Reservoir). The SFPUC would implement conservation, water recycling, and groundwater supply programs in the SFPUC retail service area to achieve the equivalent of 10 mgd of supply per year, in all years. These programs would be in addition to demand management and conservation measures already accounted for in the 2030 purchase requests for the retail service area.

In most years, the SFPUC could serve the projected 2030 water purchases of 300 mgd with its existing sources of water supply; however, these sources alone have not allowed for full water deliveries during past droughts, and they would be insufficient during future droughts as purchase requests increase. The SFPUC proposes to serve this 2030 need for increased system firm yield (i.e., water supply during a drought scenario) with a combination of conservation, water recycling, and groundwater programs in the SFPUC retail service area; water transfers (29,350 acre-feet per year) from the Turlock Irrigation District (TID) and Modesto Irrigation District (MID); a groundwater conjunctive-use program, incorporating the Westside Basin Groundwater Program; and restoration of reservoir operating capacity at Crystal Springs and Calaveras Reservoirs. Systemwide rationing is limited to no more than 20 percent in any year, with a firm yield of 256 mgd throughout an extended drought.

2.1 Water Deliveries and Drought Response Actions

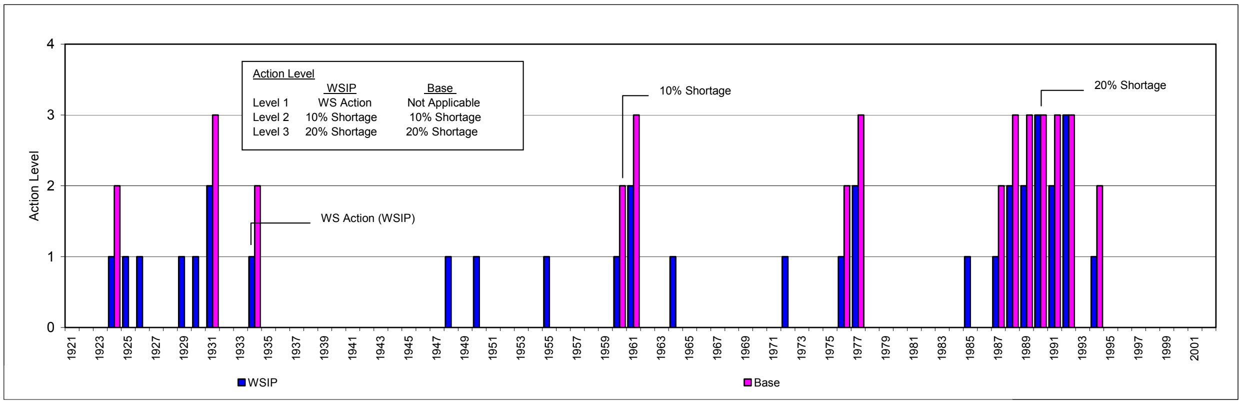
With a current systemwide purchase request of approximately 265 mgd, the regional water system cannot provide full deliveries during all anticipated drought sequences. Drought response actions (delivery shortages) are necessary at the onset of a drought to provide a viable, albeit reduced, supply throughout the duration of a drought. Because the regional water system has limited current resources, rationing of the SFPUC supply by more than 20 percent may be required during an extended drought. With the proposed program, the purchase requests would increase from 265 mgd to 300 mgd, with 10 mgd of these requests satisfied by conservation, recycling, and groundwater programs in the city of San Francisco. In the future, the system would experience a net demand of 290 mgd. The additional net demand and increase in the water supply reliability of the regional water system would be served by the water supply programs described above. Table 1-1 compares the drought response actions for the proposed program and base (Calaveras constrained) settings. Figure 2.1-1 illustrates the drought response actions for the simulated 82-year historical period (1921-2002).

In Figure 2.1-1, years with bars showing a “1” or greater level of action indicate periods when a supplemental water supply action is initiated. In the WSIP setting, the action is the use of the Westside Basin Groundwater Program to supplement SFPUC water deliveries. The water transfer from MID/TID is also occurring during these periods. Action levels greater than “1” indicate the imposition of delivery shortages (rationing) to SFPUC customers.

Figure 2.1-1

APPENDIX O1

Drought Response Actions – WSIP and Base



In modeling parlance, there is no level 1 action in the base setting. Without supplemental resources, the existing system only has the delivery shortage measure available to cope with drought. This shortage measure is imposed during level 2 (10 percent) and level 3 (20 percent). These percentages of shortage are applied to both the WSIP and the base settings for these action levels. As evidenced in Figure 2.1-1, rationing would be required more frequently and with greater severity (level 2 and level 3 actions) in the base setting.

Figure 2.1-1 illustrates that, when compared to the base setting, the WSIP setting triggers the supplemental resource (Westside Basin Groundwater Program) at an early indication of drought, and during periods when in the base setting there were no supplemental resources available to the system. The utilization of the supplemental resource during these times results in the elimination or reduction, or at least a non-increase in the severity, of delivery shortage.

Although not illustrated in Figure 2.1-1, Table 1-1 shows the delivery shortages anticipated during the entire SFPUC design drought. Shortages during the design drought with the WSIP are maintained within the objective to limit the severity of shortage to no more than 20 percent. With the existing system (Calaveras and Crystal Springs Reservoirs constrained), the 20-percent-limitation (cap) objective cannot be achieved during the last 18 months of the design drought, and a 25-percent shortage is applied. The system's yield in the base setting is 219 mgd.

The difference in water deliveries between the proposed program and the base settings is shown chronologically for the 82-year simulation in Table 2.1-1. The differences all indicate an increase in deliveries due to an increase in the level of purchase requests, and an increase in the reliability of delivery. The annual (fiscal-year-based) increase of approximately 9.1 million gallons represents the basic increase in delivery associated with an increase in purchase requests from 265 mgd to 290 mgd. The years that show other levels of additional deliveries illustrate the increase in purchase requests and represent years when shortages are reduced in the WSIP setting compared to the base setting.

2.2 Diversions from Tuolumne River

The metric for illustrating the SFPUC diversions from the Tuolumne River Basin is the flow through the San Joaquin Pipeline (SJPL). Table 2.2-1 illustrates the difference in diversions to the SJPL between the proposed program and the base settings. Evident in the operation is the increase in summer diversions associated with an increase in the conveyance capacity of the SJPL. Regardless of an increase in purchase requests, the availability of increased conveyance capacity would increase diversions during the summer to retain storage in the Bay Area reservoirs, typically exercising the SJPL at its maximum capacity. The increase in purchase requests would require the utilization of the maximum capacity for a longer period into the fall. Generally, fewer diversions would occur during the late fall and early winter because of the lesser drawdown of the Bay Area reservoirs (requiring less replenishment), and because systematic maintenance within Hetch Hetchy facilities (lessening available conveyance capacity) would impair diversions in the WSIP setting. The increase in diversions during the winter and spring would

APPENDIX O1

result from the need to replenish Bay Area reservoir storage after the maintenance period, serve increased purchase requests, and top off Bay Area reservoir storage prior to summer. The difference in SJPL diversions between the WSIP setting and the base setting is illustrated in Figure 2.2-1. The difference in average monthly diversions through the SJPL is shown by year type for the 82-year simulation period.

Table 2.2-2 illustrates the average monthly diversions through the SJPL, by year type, for the 82-year simulation period for the proposed program and the base settings. The table illustrates a trend of diverting less water from the Tuolumne River Basin in wetter years (as Bay Area reservoir watersheds provide more supply during those years) than in drier years.

2.3 Hetch Hetchy Reservoir and Releases

The additional draw of water for the additional deliveries occurring under the WSIP would generally result in an increase in draw from Hetch Hetchy Reservoir. Figure 2.3-1 illustrates a chronological trace of the simulation of Hetch Hetchy Reservoir storage and stream releases. Shown in Figure 2.3-1 are the results for the WSIP and base settings. Supplementing the Figure 2.3-1 representation of Hetch Hetchy Reservoir storage are Table 2.3-1, Hetch Hetchy Reservoir Storage (WSIP); Table 2.3-2, Hetch Hetchy Reservoir Storage (Base); and Table 2.3-3, Difference in Hetch Hetchy Reservoir Storage (WSIP minus Base).

APPENDIX O1

Table 2.3-3 illustrates the difference in Hetch Hetchy Reservoir storage between the WSIP and base settings. Immediately after Hetch Hetchy Reservoir is filled (May or June, and then continuing through July), occasional differences in storage would occur, typically during a multi-year drought sequence or during an occasional single year when the reservoir does not fill. No reduction in yearly storage during that period would indicate that the same amount of water is being passed through the reservoir, regardless of the size of the conveyance capacity of the SJPL or the purchase requests. Water not diverted to the SJPL would return to the Tuolumne River at Kirkwood Powerhouse or Moccasin Reservoir and flow to Don Pedro Reservoir. In the late summer and early fall, storage levels would consistently be slightly different (lower) between the two settings, as additional diversions to the SJPL would retain Bay Area reservoir storage. The additional storage depletion would be somewhat ameliorated later in the fall and into winter as SJPL diversions are reduced because of lower Bay Area reservoir replenishment needs and conveyance system maintenance. The storage difference would become almost neutral in December with the WSIP setting because of the additional conveyance maintenance that would occur under the WSIP (which does not occur in the base setting). The maintenance impairs diversions to the SJPL. After December, storage in the reservoir associated with the WSIP setting again would be affected as replenishment of Bay Area reservoir storage resumes following the maintenance period and because of increased purchase requests. During drier years, there is a difference in storage between the WSIP and base settings; the WSIP setting results in a lower amount of storage in the reservoir by the end of April. Figure 2.3-2 illustrates the reservoir storage, averaged by year type, for the WSIP setting. Figure 2.3-3 illustrates the average difference in storage, averaged by year type, for the two settings. Figure 2.3-4 illustrates the average monthly storage in Hetch Hetchy Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings.

Figure 2.3-2

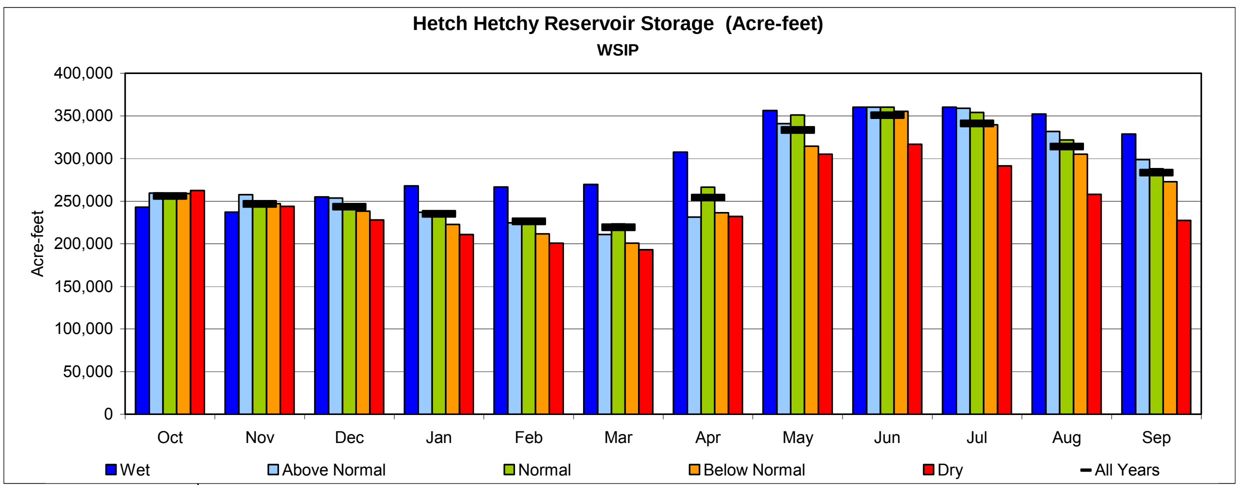

Figure 2.3-3

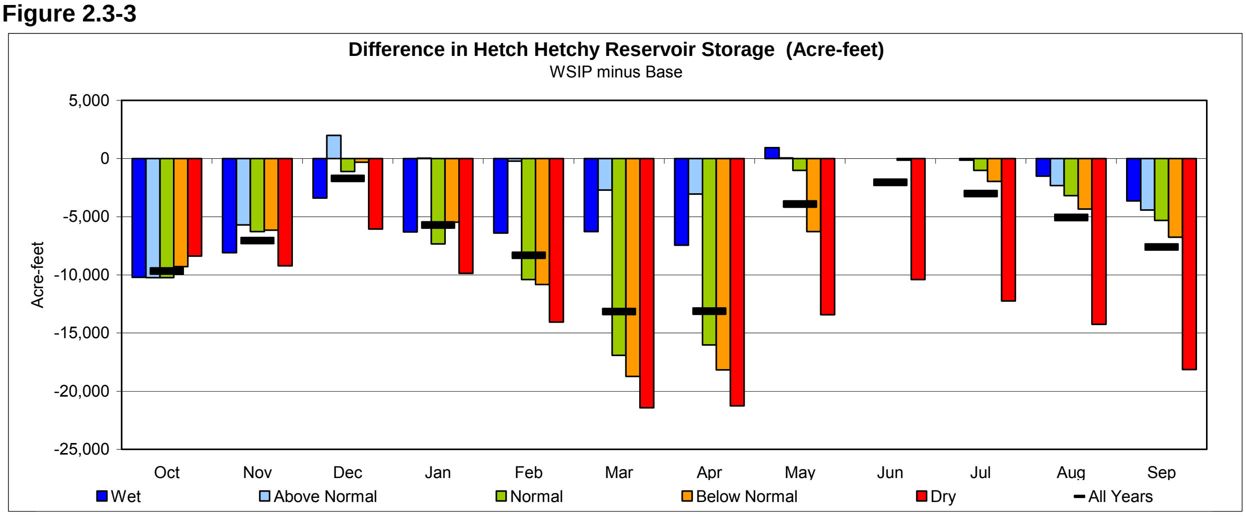

Figure 2.3-4

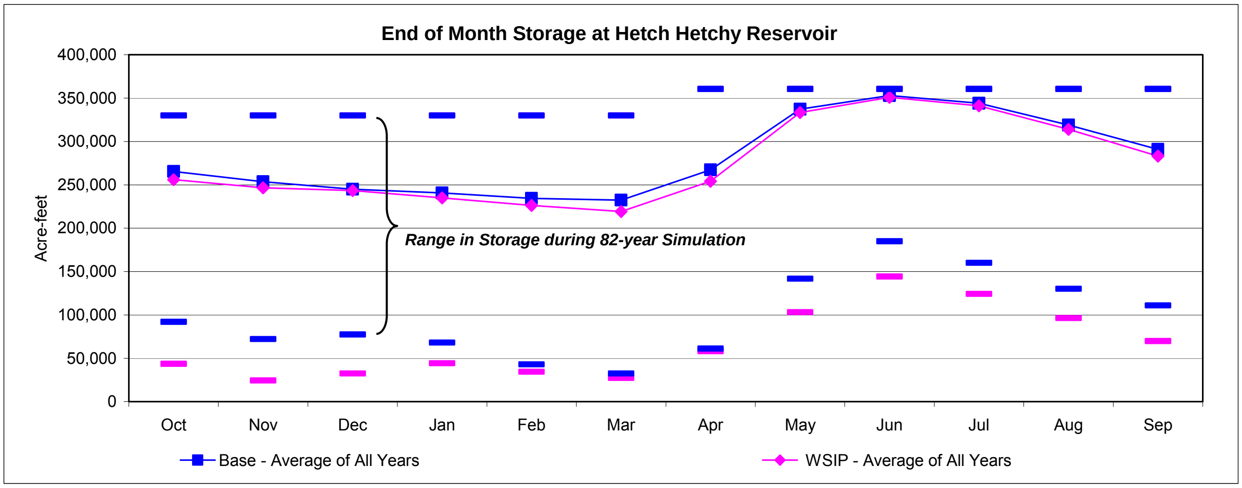

The difference in storage in Hetch Hetchy Reservoir attributed to the diversion effects of the WSIP would manifest in differences in releases from O'Shaughnessy Dam to the stream. A different amount of available reservoir space in the winter and spring due to the WSIP would lead to a different ability to regulate inflow, thus potentially changing the amount of water released to the stream (the amount which is above minimum release requirements). Figure 2.3-1 illustrates the stream releases from O'Shaughnessy Dam for the WSIP and base settings. Supplementing Figure 2.3-1 are Table 2.3-4 and Table 2.3-5, which show the stream releases from O'Shaughnessy Dam for the WSIP and base settings. Table 2.3-6 illustrates the difference in stream releases between the WSIP and base settings. Compared to the base setting, the WSIP setting typically results in a lesser stream release, predominantly during May or June, which reflects the months when releases to the stream above minimum release requirements are made in anticipation of the reservoir being filled. In a few exceptions to this circumstance, an increase in releases to the stream occurs. Several of these exceptions are considered anomalous within modeling, the result of only shifting releases from one month to another. The other exceptions occur due to the balancing of reservoir storage among the Hetch Hetchy system and the Bay Area reservoirs. The decrease in releases is the result of a more depleted reservoir, which is the result of greater demands between the settings.

Table 2.3-6 illustrates the difference in stream releases between the WSIP and base settings, expressed in terms of a monthly volume (acre-feet) of flow. The difference in monthly flow below O'Shaughnessy Dam indicates a potential change in releases between the WSIP and base settings, ranging from a decrease of approximately 40,000 acre-feet to an increase of approximately 14,900 acre-feet. Considering the manner in which releases are determined and made to the stream, quantifying the effect of these changes in terms of average monthly flow (in cubic feet per second [cfs]) is not always meaningful.[1] Assuming that a change in release volume equates to a delay or earlier initiation of releasing 6,000 acre-feet per day, the difference in stream releases from O'Shaughnessy Dam between the WSIP and base settings would range from delayed releases of up to 7 days to an addition of up to 2 days of release. Normally, the effect of a delay in release would not affect the year's peak stream release rate during a year.

1 See "Estimated Effect of WSIP on Daily Releases below Hetch Hetchy Reservoir," Memorandum by Daniel B. Steiner, December 31, 2006.

APPENDIX O1

2.4 Lake Lloyd and Lake Eleanor

Compared to the operation in the base setting, the operation of Lake Lloyd and Lake Eleanor are simulated to be only slightly different in the WSIP setting. Figure 2.4-1 illustrates a chronological trace of the simulation of Lake Lloyd storage and stream releases. Figure 2.4-1 shows the results for the WSIP and base settings. The operation resulting for the WSIP setting is essentially the same as for the base setting, except during the prolonged drought of 1987-1992. During this drought period, there is a greater draw from Hetch Hetchy Reservoir in the WSIP setting compared to the base setting. The additional draw of water reduces the amount of water released from Hetch Hetchy Reservoir to Don Pedro Reservoir in the WSIP setting, which, to satisfy MID/TID entitlements to inflow, is met with additional releases from Lake Lloyd.

Figure 2.4-2 illustrates an almost identical operation of Lake Eleanor between the WSIP and base settings. Any difference that occurs in the Lake Eleanor operation would be caused by a small change in operation at Lake Lloyd that would affect the operation of the Cherry-Eleanor Tunnel between the two watersheds. Any difference that occurs in the simulations is associated more with modeling discretion than with any substantive likely difference in operation.

Supplementing the Figure 2.4-1 representation of Lake Lloyd stream releases is Table 2.4-1, which illustrates the differences in stream releases between the WSIP and base settings. The one notable difference in operation for the 82-year simulation occurs during the year following the rare 1987-1992 drought sequence, when the additional draw from Lake Lloyd storage described above would require replenishment. In this one occurrence, the releases to the stream above the minimum release requirement that would occur in the base setting would not occur in the WSIP setting. Table 2.4-2 illustrates average releases by year type for the WSIP and base settings, and shows almost no difference in releases between the two settings.

2.5 Flow below the Tuolumne River and Cherry River Confluence

The flow that occurs below the confluence of the Tuolumne River and Cherry River is considered important to recreational activity (whitewater rafting) during the May-through-September period. To estimate the effect of the WSIP on the occurrence of flow at this location, HH/LSM monthly volumetric flow results were post-processed to reflect the daily and hourly shaping potential currently exercised by Hetch Hetchy operators to satisfy water and power objectives while accommodating the desires of recreational interests. Figure 2.5-1 and Figure 2.5-2 illustrate the controlled flow below Hetch Hetchy facilities below the confluence of the Tuolumne and Cherry Rivers, averaged by year type, for the WSIP and base settings. Illustrated are the combined flow elements of: (1) stream releases from O'Shaughnessy Dam, Lake Lloyd, and Lake Eleanor; (2) the return of Canyon Tunnel diversions through Kirkwood Powerhouse that exceed the Mountain Tunnel diversion; and (3) diversions through Holm Powerhouse. For this analysis, the monthly volumes of diversion through Holm Powerhouse have been shaped into a release of 4 hours per day for 6 days a week. The other flow elements represent the average daily flow rate associated with the monthly volume of flow. Figure 2.5-1 and Figure 2.5-2 illustrate that the HH/LSM operation protocols for reservoir operation incidentally result in approximately 1,000 cfs of flow below the confluence if Holm Powerhouse releases are shaped. This opportunity occurs in both the WSIP and base settings. The flow rates illustrated in this analysis do not reflect either the occasional shaping opportunities that occur with Kirkwood Powerhouse releases or the existence of unregulated flow that enters the streams below O'Shaughnessy Dam, Lake Lloyd, and Lake Eleanor; both of these factors would increase the illustrated flow rate. The difference in flow between the two settings that could occur during the concentrated period of flow is illustrated in Figure 2.5-3.

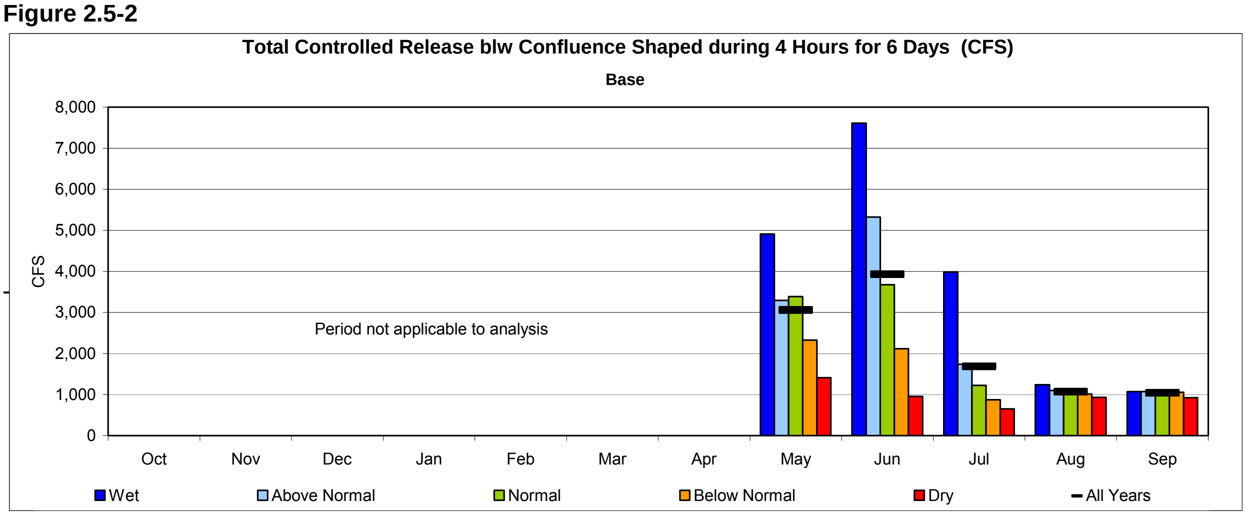

Figure 2.5-3

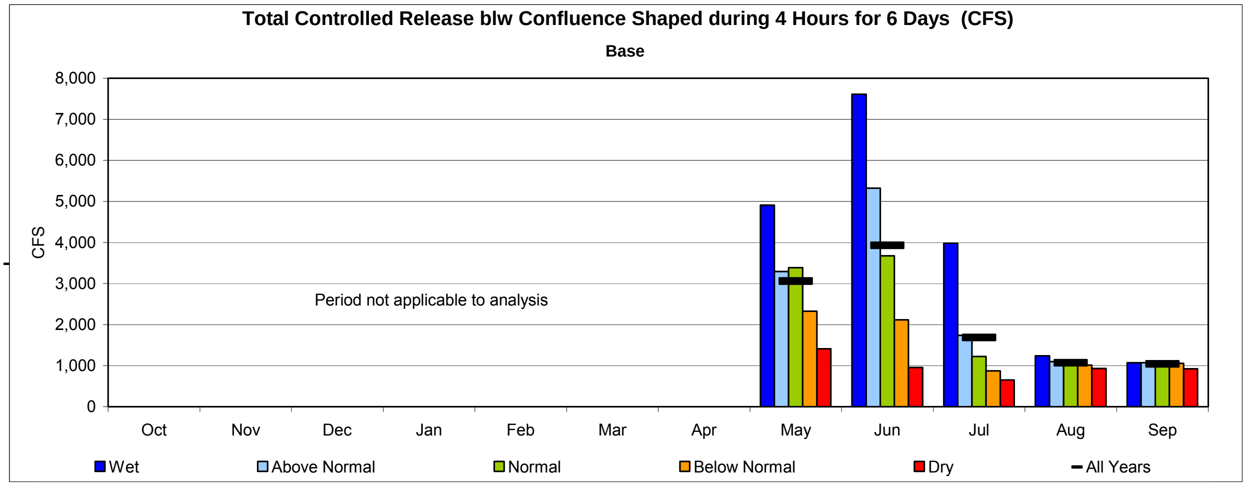

More detailed review of the 82-year simulation of operations indicates that in only one month of the simulation do circumstances in the WSIP setting result in the shaped flow crossing the threshold to below 1,000 cfs, compared to levels greater than 1,000 cfs in the base setting. In both the WSIP and base settings, in some dry and critical years, circumstances could result in a shaped flow of less than 1,000 cfs; however, results indicate that the WSIP setting would rarely increase the frequency of such an occurrence.

2.6 Don Pedro Reservoir and La Grange Releases

A change in Don Pedro Reservoir operation is caused by changes in inflow to the reservoir. The changes in inflow to the reservoir are the result of net changes within the operation of the upstream SFPUC facilities, described previously, and other changes in SFPUC operations associated with diversions to the Holm, Kirkwood, and Moccasin Powerhouses. Figure 2.6-1 illustrates a chronological trace of the simulation of Don Pedro Reservoir storage and Tuolumne River stream releases from La Grange Dam. Figure 2.6-1 presents the results for the WSIP and base settings.

Supplementing the Figure 2.6-1 representation of Don Pedro Reservoir storage are Table 2.6-1, Don Pedro Reservoir Storage (WSIP); Table 2.6-2, Don Pedro Reservoir (Base); and Table 2.6-3, Difference in Don Pedro Reservoir Storage (WSIP minus Base). The results illustrate that, throughout many years, the storage in Don Pedro Reservoir associated with the WSIP setting would differ from the storage in the base setting, and that this difference would almost always be less storage. Compared to the base setting, the differences in storage (reductions) indicate that inflow to Don Pedro Reservoir would decrease due to greater SFPUC demands and SJPL diversions in the WSIP setting. The decreases in inflow typically occur from winter through early summer. Table 2.6-4 illustrates the difference in inflow to Don Pedro Reservoir between the WSIP and base settings. Generally, the difference is an annual amount of about 27,000 acre-feet, approximating the additional delivery of the SFPUC. The season of inflow reduction is associated with the direct increase in diversions to the SJPL and the replenishment operation of Hetch Hetchy Reservoir. Figure 2.6-2 illustrates the seasonal change in Don Pedro Reservoir inflow, averaged by year type.

Figure 2.6-2

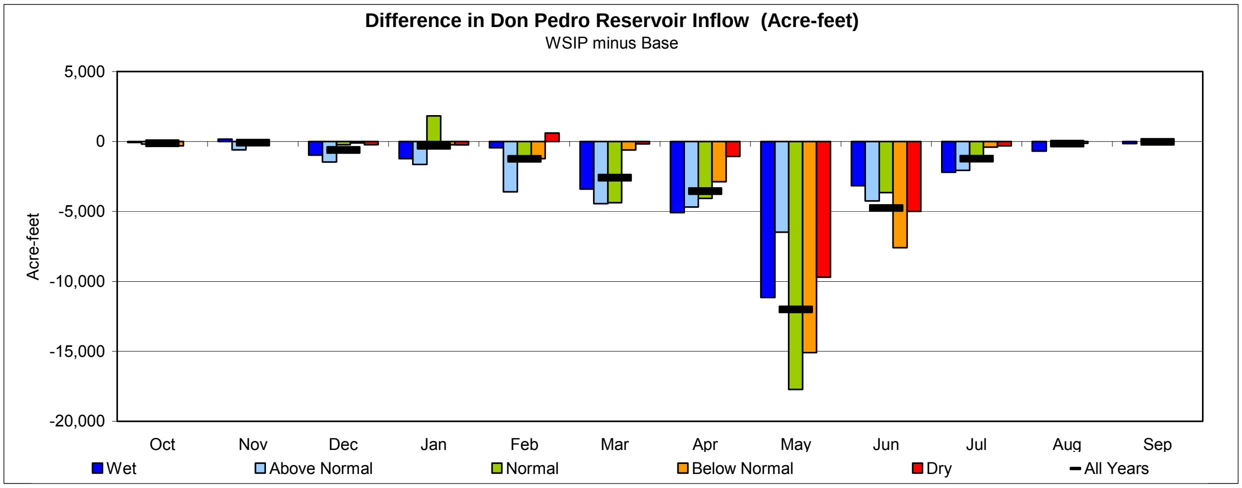

Figure 2.6-1 and Table 2.6-3 illustrate that, during drought sequences, the reduction in inflow to Don Pedro Reservoir can accumulate from year to year. Compared to the base setting, the WSIP would result in lower Don Pedro Reservoir storage during some part of most years, and more predominantly during multi-year drought periods. Figure 2.6-3 illustrates the Don Pedro Reservoir storage for the WSIP setting, averaged by year type. Figure 2.6-4 illustrates the difference in reservoir storage, averaged by year type, in comparing the WSIP and base-Calaveras constrained settings. Also shown is the average difference in storage for the two settings during the 82-year simulation.

Table 2.6-3 illustrates that, in some years (approximately one-third of the years, i.e., the wettest of years), the storage in Don Pedro Reservoir would not be substantially different, because large inflows to the reservoir during these years would require the management of storage (release of flow above minimum stream requirements) to satisfy flood control requirements. During the other years, the reduction in storage could range from a single year's additional diversions by the SFPUC to over 245,000 acre-feet (1936) from the accumulation of several years of additional diversions by the SFPUC. For example, the greatest draw from reservoir storage occurs during the drought of 1976-1977 (during which the WSIP would not cause an incremental additional draw from storage), and the greatest difference in reservoir draw between the base and the WSIP settings occurs during the years of the 1928-1935 drought.

Figure 2.6-5 illustrates the average monthly storage in Don Pedro Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings. The difference in storage in Don Pedro Reservoir attributed to the upstream effects of the WSIP would affect releases from La Grange Dam to the stream. A difference in the amount of available reservoir space in the winter and spring due to the WSIP would lead to a difference in the ability to regulate inflow, thus potentially changing the amount of water released to the stream that is above minimum release requirements. During periods when inflow differs and Don Pedro Reservoir is at maximum storage capacity within the flood control storage limitation, a change in inflow would directly manifest as a change in releases from La Grange Dam (a change in either more or less flow). Figure 2.6-1 illustrates the stream releases from La Grange Dam for the WSIP and base settings.

Figure 2.6-3

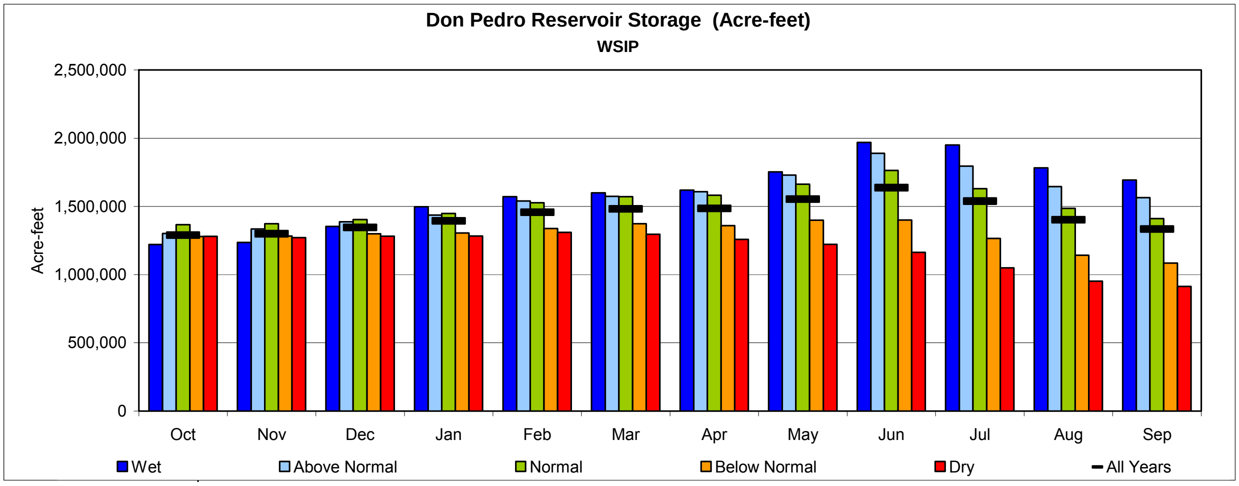

Figure 2.6-4

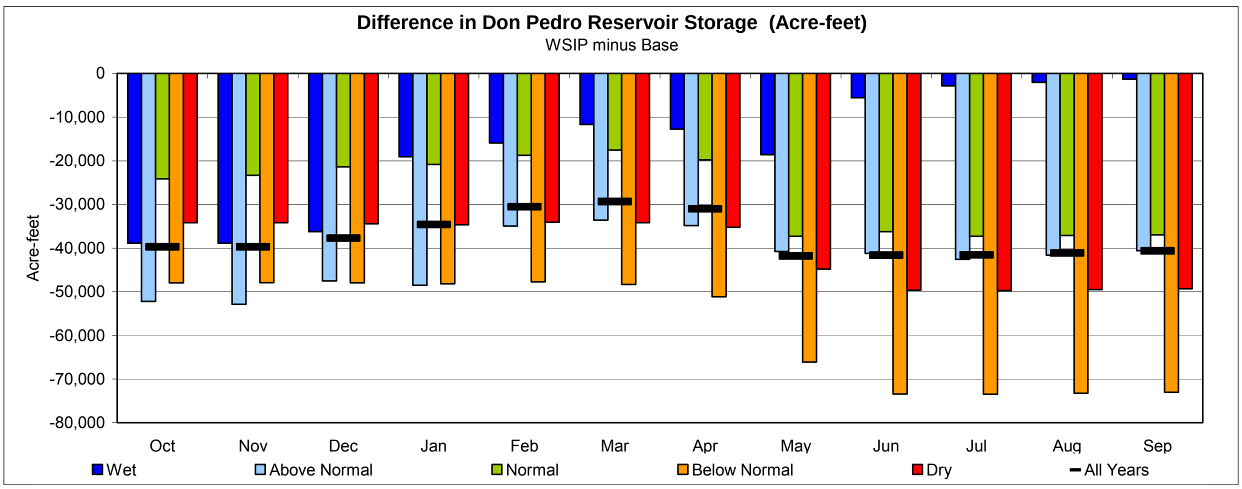

Figure 2.6-5

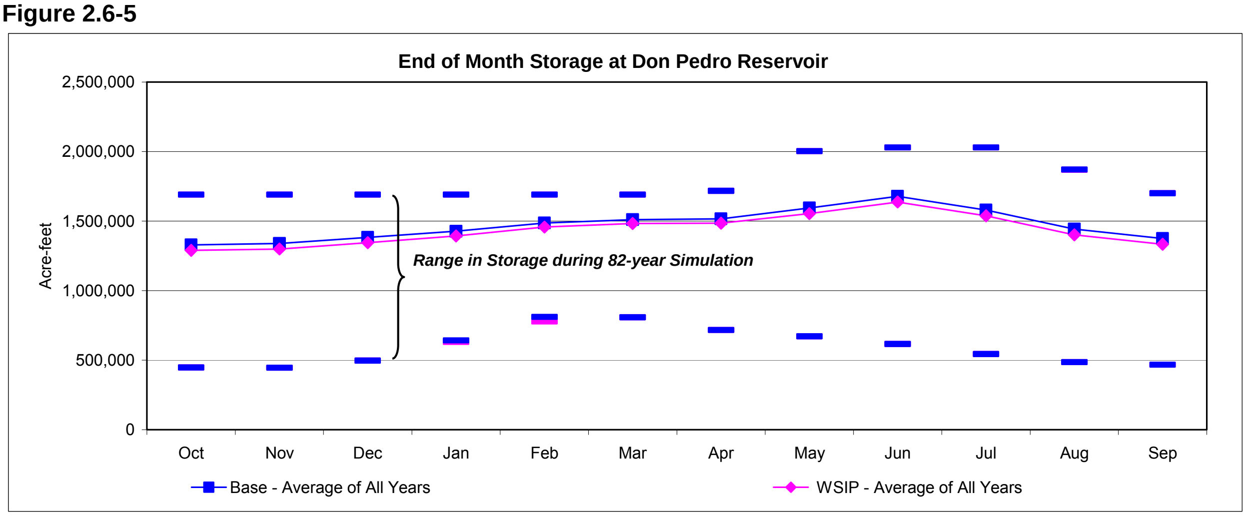

APPENDIX O1

Supplementing Figure 2.6-1 are Table 2.6-5 and Table 2.6-6, which illustrate the releases to the Tuolumne River from La Grange Dam for the WSIP and base settings. Table 2.6-7 shows the difference in stream releases between the WSIP and base settings. Consistent with the periods showing changes in Don Pedro Reservoir storage, stream releases following the drawdown periods would indicate a reduction. The additional depletion of reservoir storage would manifest as a reduction in subsequent releases below La Grange Dam to replenish reservoir storage. The same information shown in Table 2.6-7 is illustrated in Table 2.6-8, arranged in descending order based on the San Joaquin River Index. The differences in releases to the Tuolumne River from La Grange Dam would occur only when there would otherwise be releases in excess of minimum Federal Energy Regulatory Commission (FERC) flow requirements, typically during wetter years. Occasional minor reductions in releases would also occur during winter, when the direct diversion of additional water by the SFPUC would lead to a commensurate reduction in inflow to Don Pedro Reservoir. If Don Pedro Reservoir is passing inflow for flood control, a similar commensurate reduction in releases would occur. Table 2.6-7 illustrates the decrease in monthly flow below La Grange Dam that would occur, up to approximately 247,000 acre-feet in one month (February 1936). This reduction is associated with the additional replenishment of Don Pedro Reservoir caused by the additional diversions of the SFPUC during the drought of 1987-1992. The effects of the SFPUC diversions accumulate in Don Pedro Reservoir throughout the drought period. Using the assumption that a change in release volume equates to a delay or acceleration of releasing 6,000 acre-feet per day means that the difference in stream releases from La Grange Dam between the WSIP and the base settings would be a delay in releases above minimum FERC flow requirements for a period longer than a month. Normally, the delay in release would not affect the peak stream release rate during a year. However, infrequently (such as in 1993, which followed a lengthy six-year drought), the WSIP's effect on stream releases could lead to an elimination of all flow in excess of FERC requirements in the year. Such a reduction in flow would not be common and would occur only because of multi-year droughts.

Comparing the WSIP and base settings, Table 2.6-9 illustrates the releases to the Tuolumne River below La Grange Dam; their differences are provided in terms of monthly volumetric flow averaged within year types.

2.7 Calaveras and San Antonio Reservoirs, Alameda Creek, and Downstream

Compared to the base setting, Calaveras Reservoir operations would substantively change in the WSIP setting. With the restoration of Calaveras Reservoir operating capacity, the reservoir would operate with a larger storage capacity. Figure 2.7-1 illustrates a chronological trace of the simulation of Calaveras Reservoir storage and stream releases from Calaveras Dam. Shown in Figure 2.7-1 are the results for the WSIP and base settings.

The current operation of Calaveras Reservoir (base-Calaveras constrained setting) is modeled to be greatly constrained, to vary only within a limited storage range. Although a within-year cyclic operation occurs for the conservation of local watershed runoff, there is relatively little reservoir storage available for year-to-year carryover and multi-year drought use. In the WSIP setting, a greater within-year cyclic operation occurs, providing for a greater use of local watershed runoff. Also, during prolonged periods of drought (i.e., multiple years in duration), reservoir storage would be drawn to supplement runoff available to the regional system and other water supply resources. Figure 2.7-2 illustrates the average monthly storage in Calaveras Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings.

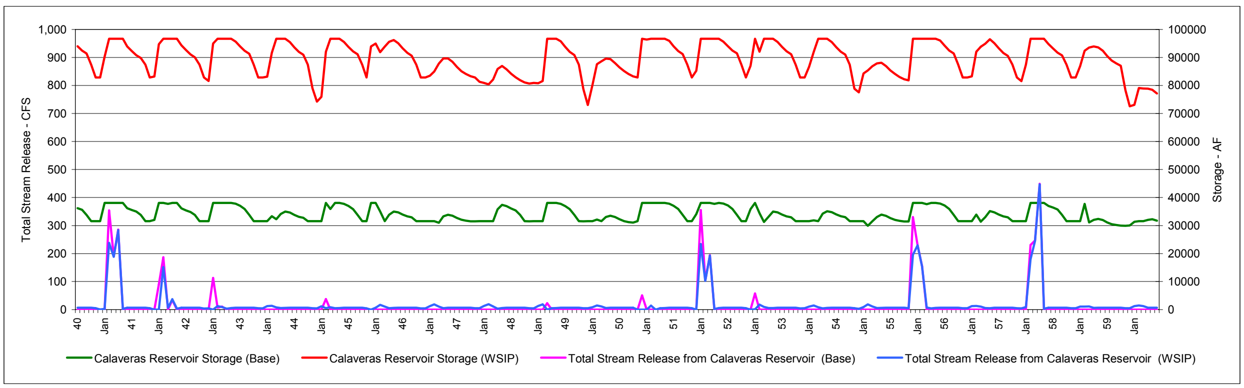
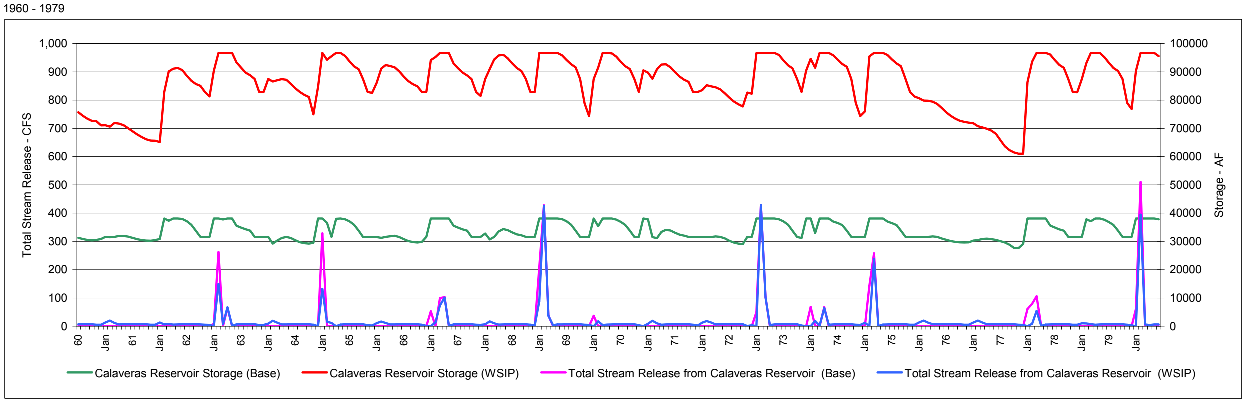
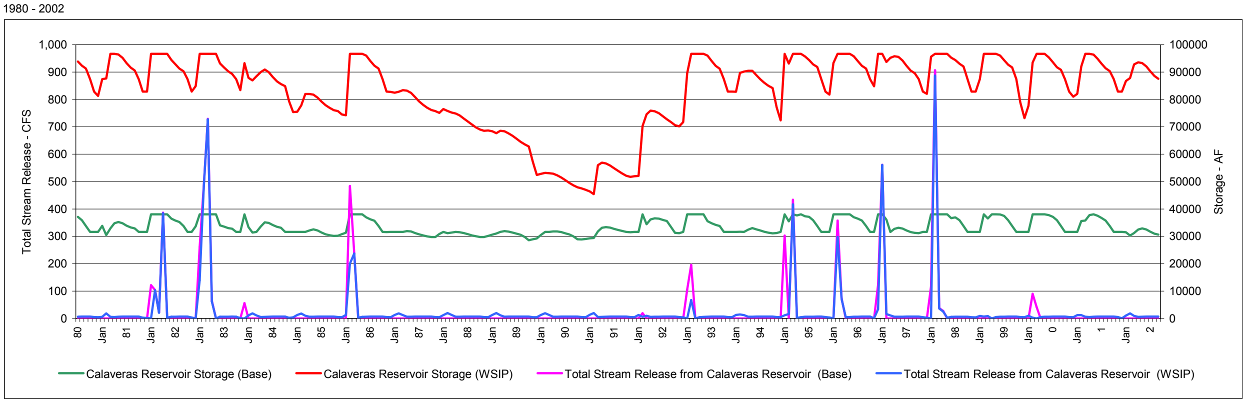
1940 - 1959



1960 - 1979

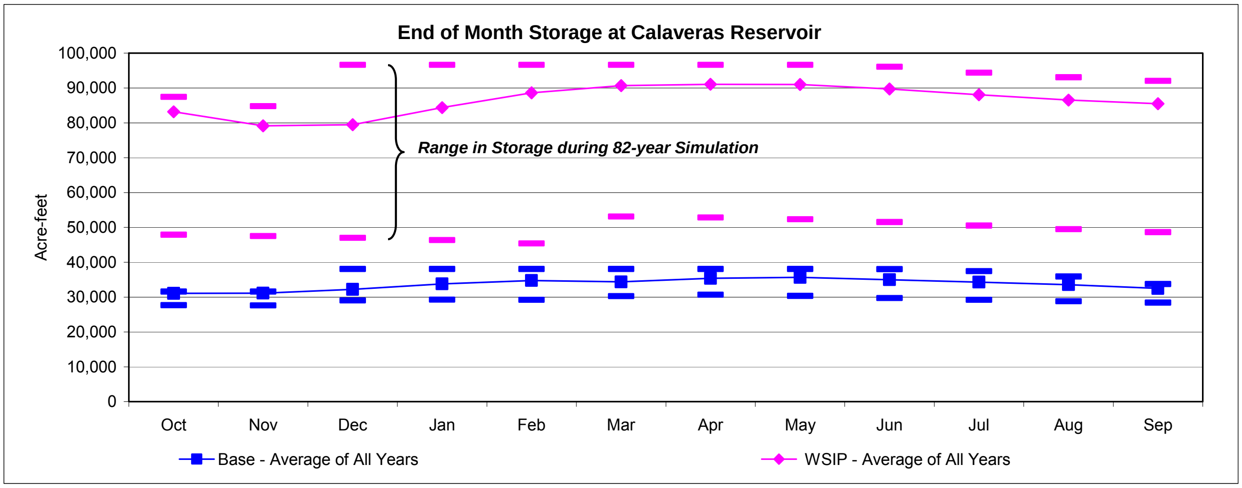


1980 - 2002



APPENDIX O1

Figure 2.7-2



In the WSIP setting (as compared to the base setting), there would be two categorical changes in releases to Calaveras Creek below Calaveras Dam: the addition of flows representing the flow objectives associated with the 1997 California Department of Fish and Game Memorandum of Understanding (MOU); and the reduction of stream releases during wetter-year/wetter-season flows due to the restored operational capacity of Calaveras Reservoir. Supplementing the Figure 2.7-1 representation of Calaveras Dam stream releases is Table 2.7-1, which illustrates releases for the WSIP and base settings and the difference in releases between the two.

Compared to the base setting, diversions from Alameda Creek to Calaveras Reservoir would increase in the WSIP setting. With the current constraints on Calaveras Reservoir storage, diversions to Calaveras Creek are rejected. With the restoration of operational storage in the reservoir, the opportunity to divert water into the reservoir would increase.

To provide a context for the amount of water diverted at the Alameda Creek Diversion Dam (ACDD), Table 2.7-2 illustrates the estimated runoff (inflow) to the dam, averaged by year type. Table 2.7-3 compares diversions to Calaveras Reservoir in the WSIP and base settings. An increase in diversions during the winter season due to WSIP operation would generally occur during normal or wetter year types, as reservoir storage space would accommodate diversions. During summer in all years and during all periods in below-normal and normal years, diversions would continue as they do currently. A few exceptions occur when diversions would be reduced from that of the base setting.

Commensurate with changes in diversions from Alameda Creek to Calaveras Reservoir would be changes in flow below the ACDD. Table 2.7-4 illustrates the flow below the ACDD for the WSIP and base settings. Table 2.7-4 shows that, opposed to diversions to Calaveras Reservoir, flow passing the ACDD would decrease in the WSIP setting. With operational capacity restored at Calaveras Reservoir, there would be more opportunity (and need) to divert Alameda Creek flows; thus, flow passing the dam would be reduced.

Flow below the confluence of Alameda Creek and Calaveras Creek is affected by releases from Calaveras Dam to the stream, flow passing the ACDD, and unregulated flow below the ACDD and Calaveras Dam. Table 2.7-5 illustrates the flow below the confluence for the WSIP and base settings, and the difference in inflow between the two. The notable differences between the WSIP and the base settings are the addition of stream flows representing the 1997 MOU and the reduction of wetter-year/wet-season flows due to the restoration of Calaveras Reservoir storage.

A flow recapture facility in Alameda Creek below Calaveras Reservoir is incorporated in the WSIP setting. This facility is assumed to recapture flows explicitly released from Calaveras Dam in the representation of the 1997 MOU. The effect of the recapture is a reduction in the flow that occurs below the confluence of Alameda and Calaveras Creeks, but only to the extent that releases were explicitly made from Calaveras Reservoir. Flows below this diversion have been estimated and noted as the flow above the Alameda and San Antonio Creek confluence. Table 2.7-6 illustrates the flow at this location for the WSIP and base settings. The flows identified at this location indicate flow occurring below the confluence of Alameda and Calaveras Creeks (described above), with the addition of estimated unregulated stream accretions between the Alameda-Calaveras Creek confluence and the Alameda-San Antonio Creek confluence minus the water assumed to be recaptured (diverted) by the SFPUC from the creek.

The difference in San Antonio Reservoir storage between the WSIP and base settings is the result of several factors, and is predominantly due to the restoration of the operational capacity of Calaveras Reservoir and the maintenance of Hetch Hetchy conveyance. Figure 2.7-3 illustrates a chronological trace of the simulation of San Antonio Reservoir storage and stream releases from the dam. Shown in Figure 2.7-3 are the results for the WSIP and base settings. In the base setting, the limited operating storage capacity at Calaveras Reservoir leads to a different operation at San Antonio Reservoir, one that draws relatively more stored water for system demands when the draw from Calaveras Reservoir is constrained due to limited storage. The resultant effect is that the WSIP setting would retain more storage in San Antonio Reservoir than occurs in the base setting. The exception to this outcome is during cyclic maintenance of Hetch Hetchy conveyance that would constrain Hetch Hetchy diversions every year, but most dramatically every fifth year. During these periods, additional water would be drawn from San Antonio Reservoir and the other Bay Area reservoirs to serve systemwide deliveries when limited or no water would be available from Hetch Hetchy. The coincidence of wet local Bay Area watershed hydrology, reservoir storage balancing among the Bay Area reservoirs, and maintenance would affect the severity of drawdown and the rate of replenishment of San Antonio Reservoir.

Also affecting the magnitude of draw from San Antonio Reservoir are modeling assumptions for the balancing of total Bay Area reservoir storage among the five major SFPUC reservoirs. The model balances storage among reservoirs by way of an input file by the modeler concerning the relative draw (percentage) from each reservoir under various storage conditions. These are discretionary inputs in the model, and the logic and relative percentages are meant to mimic the current practice and discretion of the system operators based on recognition of the physical conveyance constraints within the system and the ability of each reservoir to provide yield and water delivery security. The logic currently favors the retention of storage in the Peninsula reservoirs for security reasons, and thus the provision of additional water between the settings is balanced between San Antonio and Calaveras Reservoirs. Figure 2.7-4 illustrates the average monthly storage in San Antonio Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings.

APPENDIX O1

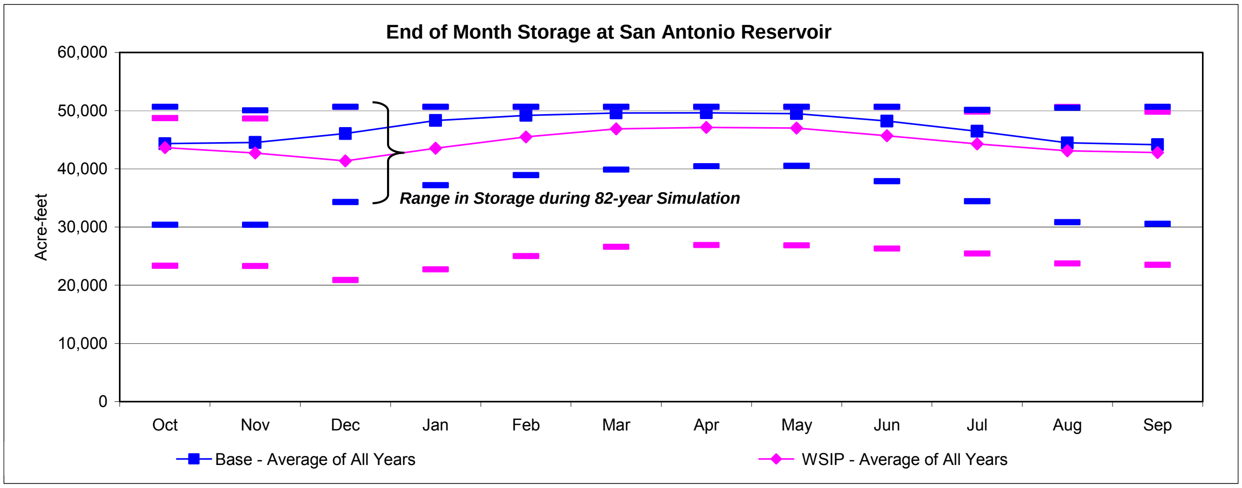
Figure 2.7-4



There would very little change in stream releases below San Antonio Reservoir between the WSIP and base settings. With storage conditions lower at some times and higher at other times, a difference in the ability to regulate reservoir inflow and avoid stream releases is expected. Given the sometimes rigid constraints within the modeling assumptions, the model will overestimate the frequency and magnitude of stream releases from San Antonio Reservoir under any of the investigated settings. The flexibility that occurs in actual operations would likely avoid most of the releases represented by the model. The modeled stream releases from San Antonio Reservoir and difference between releases for the WSIP setting and base setting are shown in Table 2.7-7. The differences between the two settings range from increases to decreases in flow, generally with decreases in releases. This modeled circumstance reflects the different resulting storage operations between the two settings, as seen in Figure 2.7-3. As described above, the model will overestimate the frequency and magnitude of releases from San Antonio Reservoir, and the actual releases from San Antonio Reservoir in any setting and the difference between settings are expected to be minor.

Flow below the confluence of Alameda and San Antonio Creeks is influenced by releases from San Antonio Reservoir and flow arriving at the location from Alameda Creek, which includes upstream impairment by SFPUC operations and facilities. Table 2.7-8 illustrates the flow below the confluence for the WSIP and base settings, and the differences in flow between the two. The differences are particularly due to the effects of restoring Calaveras Reservoir operating capacity in the WSIP setting.

2.8 Crystal Springs and San Andreas Reservoirs

Fundamental to the difference in storage operations between the WSIP setting and the base setting is the restoration of reservoir operation capacity in the WSIP setting, which does not occur in the base setting. Full capacity of the restored reservoir is 22,150 million gallons (approximately 67,980 acre-feet), and the current full operating capacity is 18,520 million gallons (approximately 56,840 acre-feet). The result is the operation of Crystal Springs Reservoir at a higher maximum storage in the WSIP setting. Figure 2.8-1 illustrates a chronological trace of the simulation of Crystal Springs Reservoir storage and stream releases from Crystal Springs Dam. Shown in Figure 2.8-1 are the results for the WSIP and base settings.

Compared to the base setting, the WSIP setting would generally result in a shifting of the maximum storage level and the normal range of reservoir operation to a greater volume (elevation); the lower end of the monthly operating range would normally be greater in storage than in the base setting. In some years, the variation from maximum storage to minimum storage may increase in the WSIP setting. The cyclic greater draw from storage in the WSIP setting every fifth year is associated with the maintenance of the Hetch Hetchy conveyance system.

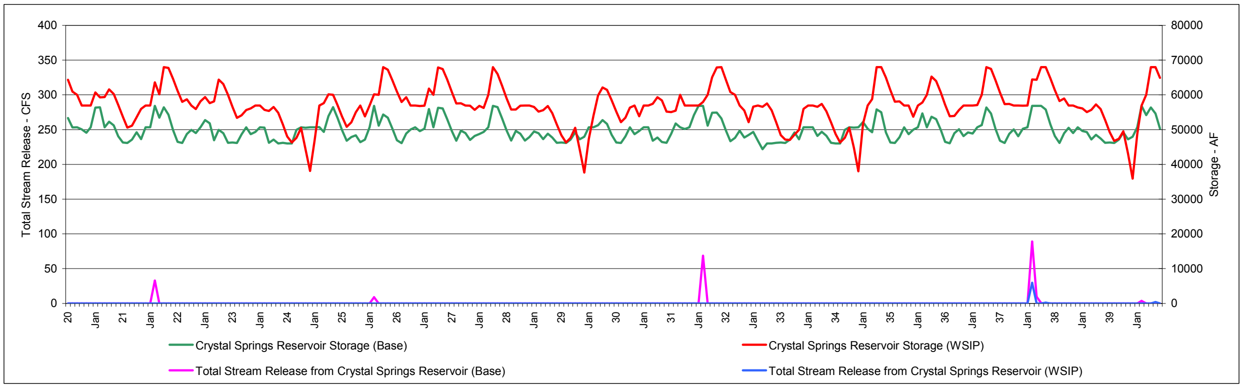
Figure 2.8-2 illustrates the average monthly storage in Crystal Springs Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings. Consistent with the discussion above, the WSIP setting would result in reservoir storage operating at a higher average and higher upper-range than the base setting. This circumstance predominantly occurs due to the restoration of the operating capacity of Crystal Springs Reservoir.

There is minimal difference in stream releases between the WSIP and the base setting (which could be either an increase or decrease in the release). The potential difference is attributed to whether the resulting storage in the reservoir is higher or lower between the two settings. Part of the difference in modeled Crystal Springs Reservoir storage is due to modeling assumptions for the proportionate management of storage among the Bay Area reservoirs, and the coincidence of constrained conveyance flow rates. In actual operations, it is anticipated that system operators would manage the reservoir system such that stream releases would be minimal under any setting and essentially no difference would occur between the WSIP and base settings.

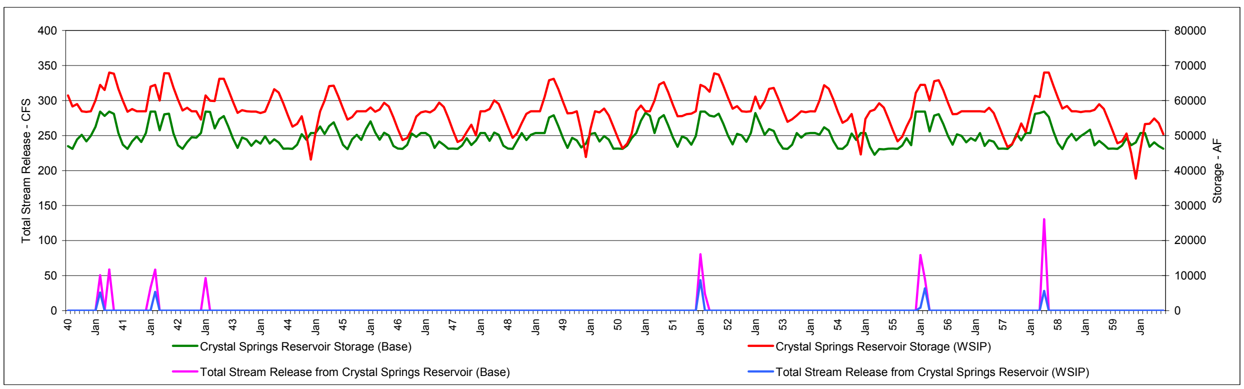
APPENDIX O1

Figure 2.8-1
Crystal Springs Reservoir Storage and Release

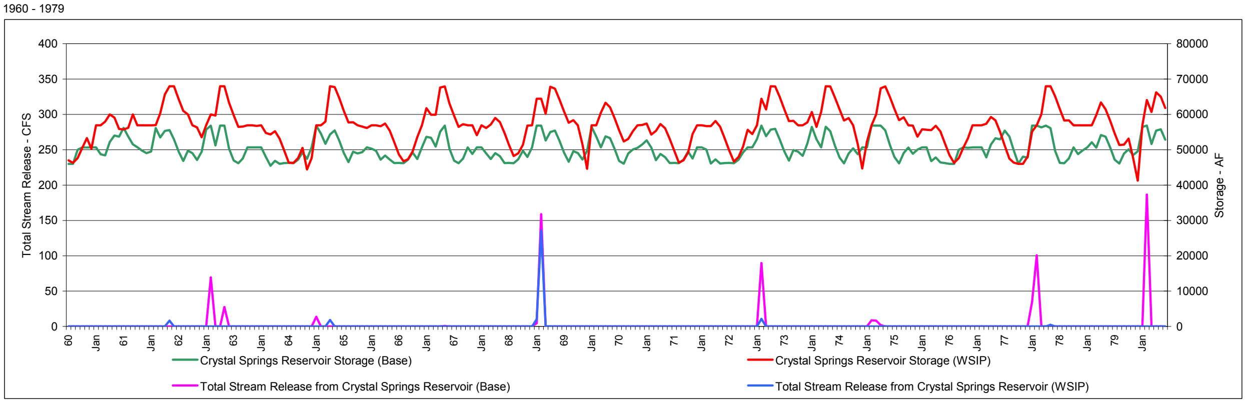
1920 - 1939



1940 - 1959



1960 - 1979



1980 - 2002

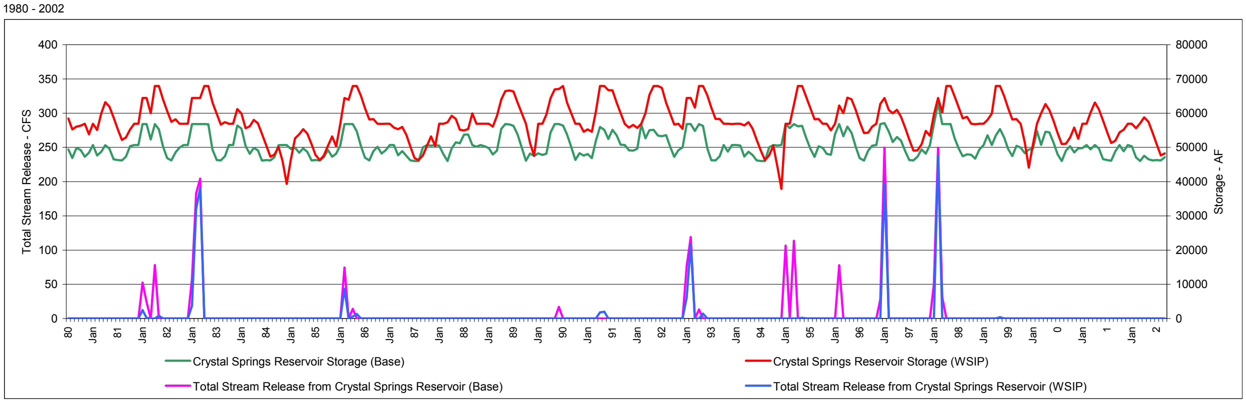


Figure 2.8-2

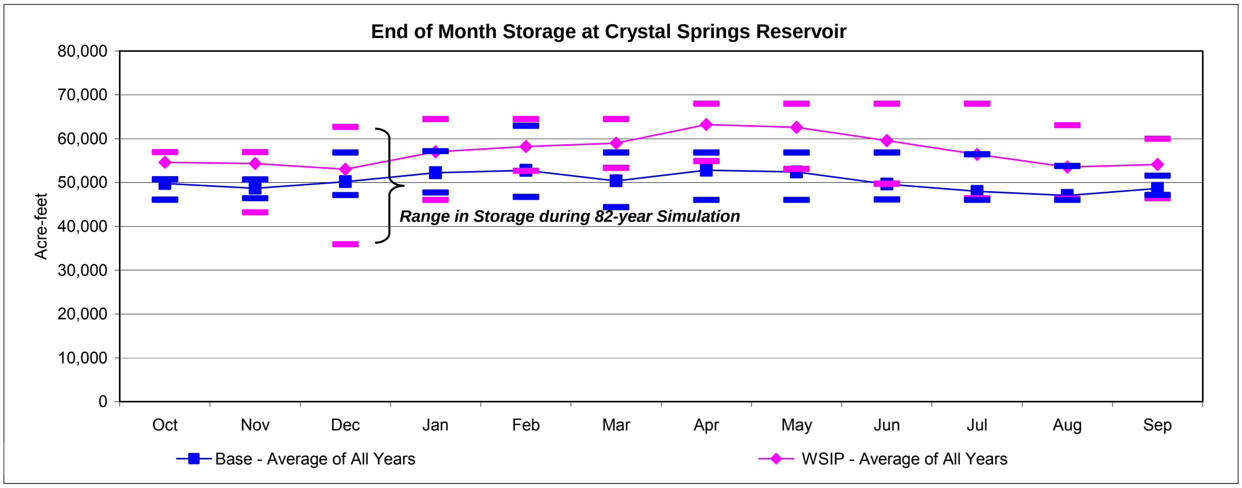

Table 2.8-1 illustrates the stream releases for the WSIP and base settings, and the difference in modeled flows between the two settings. A greater range in Crystal Springs Reservoir operation would lead to an increased potential to regulate reservoir inflow, which would lead to less risk in needing to make stream releases. However, as described above, actual system operations will attempt to minimize releases under any setting; thus, the difference in releases between the WSIP and base setting will be minimal, if any.

San Andreas Reservoir operations would generally be the same between the WSIP and base settings. Reservoir storage would follow a systematic filling and lowering each year. Figure 2.8-3 illustrates a chronological trace of the simulation of San Andreas Reservoir storage and stream releases from Crystal Springs Dam. Shown in Figure 2.8-3 are the results for the WSIP and base settings. There are no projected stream releases from San Andreas Reservoir in any setting. Notable in Figure 2.8-3 is the difference in storage operation every fifth year. The WSIP setting storage operation differs from that in the base settings. The differences in operation arise from the assumed difference in Hetch Hetchy conveyance maintenance in each setting. In the WSIP setting, the maintenance occurs systematically every year, and to a greater degree every fifth year, which constrains the amount of Hetch Hetchy water supplied to serve water demands in the Bay Area. As discussed previously, during these winter periods, the Bay Area reservoir system accommodates the reduction in imported supply by serving the Bay Area water deliveries with the local watersheds' runoff and storage. At San Andreas Reservoir, the serving of

APPENDIX O1

Figure 2.8-3

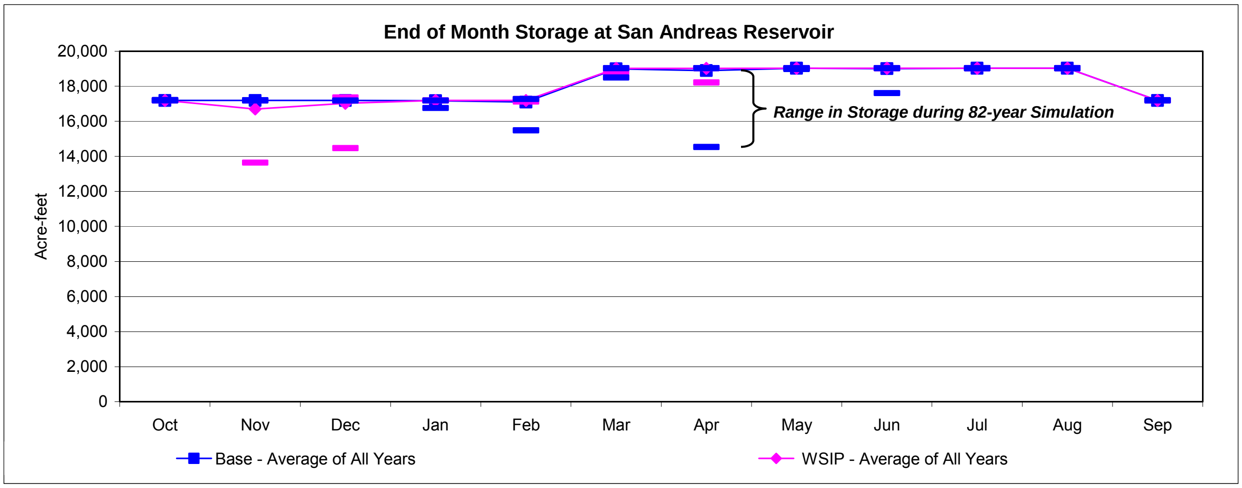
water demand affects the reservoir when additional required water production at Harry Tracy Water Treatment Plant (Harry Tracy WTP) associated with the WSIP or the base-Calaveras unconstrained setting exceeds the ability to maintain San Andreas Reservoir storage with pumping from Crystal Springs Reservoir. The model assumes that the conveyance capacity from Crystal Springs Reservoir is the same among all of the settings. The additional water demand of the WSIP setting and the current demand of the base-Calaveras unconstrained setting require additional production from Harry Tracy WTP to be drawn from San Andreas Reservoir. Figure 2.8-4 illustrates the average monthly storage in San Andreas Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings.

Figure 2.8-4



2.9 Pilarcitos Reservoir

The Coastside County Water District's (Coastside CWD) water demand and its SFPUC purchase request are projected to increase within the WSIP planning horizon of 2030. Within the context of the 2030 purchase request of 300 mgd, Coastside CWD's portion has been estimated to amount to about 3 mgd. This projected purchase request is approximately 1 mgd greater that its current purchase request. Considering the current physical constraints to deliveries from the SFPUC to Coastside CWD and the ongoing planning activities in the watershed, the precise means of serving Coastside CWD's additional purchase request (and the resultant potential changes in the operation of SFPUC facilities and their affected environs) are uncertain.[2]

Assuming a range of potential means to serve the additional purchase request from Coastside CWD, the following are potential hydrologic effects on SFPUC facilities and their affected environs:

- Due to limited yield from Pilarcitos Reservoir, additional diversions would be required from Crystal Springs Reservoir.
- If deliveries to Coastside CWD from Pilarcitos Reservoir increase during the winter season, these deliveries could potentially reduce storage in Pilarcitos Reservoir, thereby potentially reducing diversions to the San Mateo Creek watershed. Although the increased delivery would increase releases to Pilarcitos Creek from Pilarcitos Dam for a period of time, the increase would subsequently lead to a reduction in spills past Stone Dam.
- Additional wintertime deliveries could also potentially impair the ability to provide carryover storage into the summer season from Pilarcitos Reservoir, and subsequently lead to an acceleration of the beginning of the season when releases to Pilarcitos Creek from Pilarcitos Reservoir consist only of the passage of reservoir inflow.

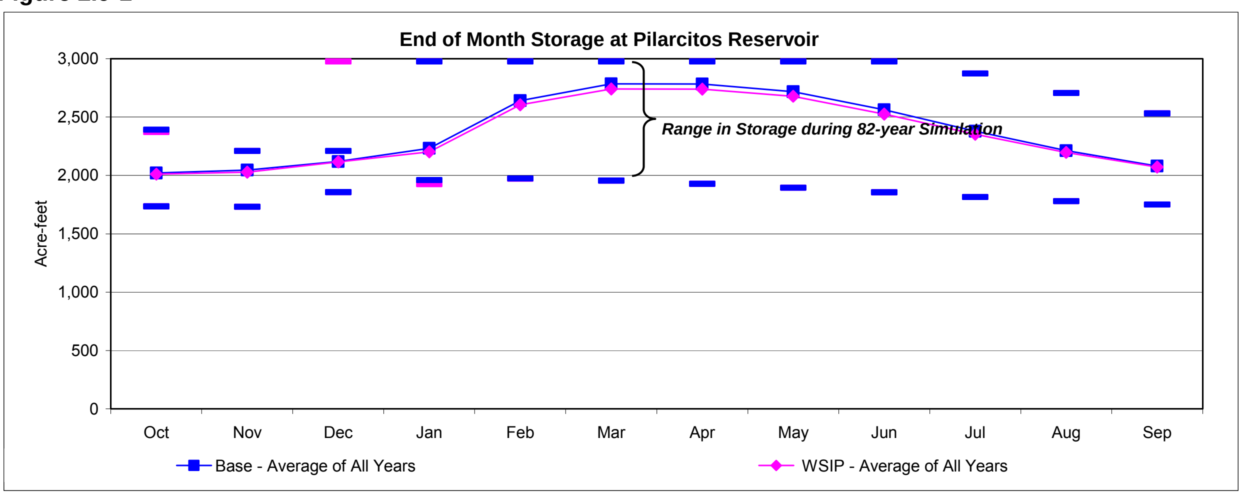
[2] See "Analysis of SFPUC Pilarcitos/Coastside County Water District Operations," Memorandum by Daniel B. Steiner, March 8, 2007.

- An increase in summertime deliveries from Pilarcitos Creek could also accelerate the beginning of the season when releases to Pilarcitos Creek from Pilarcitos Reservoir consist only of the passage of reservoir inflow.

Figure 2.9-1 illustrates the average monthly storage in Pilarcitos Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings for one possible outcome of the SFPUC providing deliveries for Coastside CWD's increase in demand. Figure 2.9-2 illustrates a chronological trace of the simulation of Pilacitos Reservoir storage and stream releases from Pilarcitos Dam. Shown in the figures are the results for the WSIP and base settings. Assumed in the operation is an increase in purchase request by Coastside CWD, distributed on a proportionate monthly pattern during the year consistent with historical SFPUC deliveries. Also assumed is a conveyance constraint of 2 mgd to Coastside CWD from the Pilarcitos Creek source of water. When the assumed monthly purchase request of Coastside CWD exceeds this conveyance constraint, Coastside CWD's request is met with deliveries from Crystal Springs Reservoir.

The effect of the assumed Coastside CWD operation in combination with the effects of the rest of the SFPUC regional system operation results in occasional differences in the storage operation of Pilarcitos Reservoir. Overall, there would be a slightly lower average storage at Pilarcitos Reservoir. Several factors contribute to the changes. Additional water is drawn from Pilarcitos Reservoir to the San Mateo Creek watershed in reaction to additional demands being served from the SFPUC system. Pilarcitos Reservoir is at times also drawn to meet the increase in demand from Coastside CWD during months (e.g., spring months) when available conveyance capacity from Stone Dam exists. Both of these additional draws from the reservoir would deplete storage below that experienced in the base setting. Pilarcitos storage would typically replenish at the expense of reservoir spills that would have occurred at a future date, and within a year storage would end the same as in the base setting, as the reservoir would still be subsequently depleted to the minimum level at the spillway crest.

Figure 2.9-1



Stream releases from Pilarcitos Dam are also shown in Figure 2.9-2. Releases can occur for diversions at Stone Dam for Coastside CWD deliveries, conveyance to the San Mateo Creek watershed (e.g., Crystal Springs Reservoir), and reservoir spills. Pilarcitos Creek typically gains flow from unregulated tributary streams and runoff below Pilarcitos Dam. The differences in flow between the WSIP setting and base setting are shown chronologically in Table 2.9-1 and summarized by monthly averages within year types in Table 2.9-2. The positive changes in flows during the winter and spring are indicative of the additional draw of water from the reservoir to serve the increased demand of Coastside CWD during the period when conveyance capacity exists from Stone Dam. The few reductions in flow during the summer are indicative of years when additional releases earlier in a year lead to the reservoir being depleted to minimum storage earlier in the year, thus reducing the amount of water released in a later month. Reductions in flow during the winter and spring are indicative of the reservoir replenishing additionally depleted storage associated with the WSIP setting.

The effect of the WSIP on Pilarcitos Creek flows below Stone Dam is different than the effect on flows below Pilarictos Dam. Figure 2.9-3 illustrates the chronological trace of inflow to Stone Dam, which includes releases from Pilarcitos Dam to Pilarcitos Creek and unregulated flow occurring to the stream below Pilarcitos Dam, and releases (spills) from Stone Dam to Pilarcitos Creek. Shown in the figure are the results for the WSIP setting and the base setting. The flow past Stone Dam is typically minor (zero in modeling results, but may be measurable in terms of leakage and seepage past the dam), as inflow to the dam is diverted to Coastside CWD or to the San Mateo watershed. Releases past Stone Dam are typically the result of unregulated flow below Pilarcitos Dam exceeding the delivery needs of Coastside CWD at a time when the storage level at Crystal Springs Reservoir rejects the water from the Pilarcitos watershed.

The changes in flow below Stone Dam would typically occur during the rainy season between the months of January and March, in at least one month during about half of the years. Table 2.9-3 summarizes the results of the WSIP and base settings in terms of average monthly flows by year type, and the average differences in flow between the two settings.

Memorandum

Subject: **HH/LSM Assumptions and Results – CEQA Alternatives Modified WSIP**

From: **Daniel B. Steiner**

Date: **April 29, 2008**

1. Introduction

This memorandum summarizes assumptions for, and discusses the interpretation of, the HH/LSM results for the simulation of the CEQA alternative referred to as the Modified WSIP Alternative. The Draft PEIR analyzed six CEQA alternatives: (1) No Program, (2) No Purchase Request Increase, (3) Aggressive Conservation/Water Recycling and Local Groundwater, (4) Lower Tuolumne River Diversion, (5) Year-round Desalination at Oceanside Alternative, and (6) Regional Desalination for Drought. The scenarios represent CEQA program alternatives that vary from the WSIP on key program components in a manner expected to avoid or reduce potentially significant effects of the proposed program. The Modified WSIP Alternative supplements the previously described analyses. Tables 1-1 and 1-2 summarize the components, various modeling assumptions, and performance and hydrologic results for the Modified WSIP Alternative in comparison to the modeled existing (2005) base setting (with Calaveras Reservoir constrained by DSOD restrictions) and the WSIP setting.

The hydrology that would result under this alternative is primarily discussed in terms of a comparison to the proposed program and contrasted to the baseline condition of the PEIR, namely the simulated current (2005) operation of the SFPUC regional water system assuming that the Calaveras and Crystal Springs Reservoirs operation are constrained by DSOD restrictions. Only primary hydrologic parameters such as projected water deliveries, reservoir storage, and stream flows are compared, and only those parameters that have been identified as key hydrologic factors that could lead to environmental impacts are illustrated.

APPENDIX O2

Notes for Table 1-1 and Table 1-2

1. Baseline condition represents the existing conditions at the time of NOP publication in September 2005. This is the baseline used to assess WSIP program impacts and impact significance. This setting is indicative of DSOD restrictions on Calaveras and Crystal Springs Reservoirs.

2. N/A

3. These scenarios represent CEQA alternatives that vary from the WSIP on key components in a manner expected to avoid or reduce potentially significant effects of the proposed program.

4. The time horizon for the setting of the scenario. The baseline condition scenario is depicted for recent conditions, while the proposed WSIP, variants, and alternatives are depicted for the future at full buildout and implementation (i.e., conditions in the year 2030).

5. HH/LSM simulation study name.

6. The customer purchase request (demand) information is based on the demand and request studies prepared by the SFPUC in coordination with the wholesale customers. This demand on the regional water system includes both the SFPUC retail customers and wholesale customers. The current (2005) average annual demand is 265 mgd and the projected 2030 average annual demand is 300 mgd, assuming the SFPUC adopts the updated wholesale customer purchase requests as part of renewing the Master Sales Agreement with these customers (due in 2009).

7. Certain scenarios include development of additional water supply from a combination of recycled water projects, groundwater projects, and conservation, utilized every year and not subject to reduction during drought.

8. The average annual demand for supplies from the combination of SFPUC local watershed, Tuolumne River and programs not included in the regional water conservation, recycling, and groundwater programs shown.

9. Modeled results for SFPUC deliveries, with supplies added for regional water conservation, recycling, and groundwater programs. Total deliveries and supply will be less than full customer purchase requests due to rationing in some years.

10. Shows only the features that affect hydrologic results of the system operation simulations. Additional projects are included in the WSIP, variants and alternatives.

11. Illustrates the frequency and severity of water supply action or the severity of systemwide rationing. Only years when variable water supply component is implemented or rationing occurs are shown. "DD" illustrates the shortage results for years included in the prospective drought period of the SFPUC design drought. These years contribute to establishing system operation protocols but are not included in the hydrologic assessment analyses.

12. Rationing policy cap: The SFPUC WSIP level of service goal is to maintain rationing on the regional system at no more than 20% during any one year of the drought. Some alternatives do not achieve this level of service goal. Performance is indicated for the design drought ("DD") sequence and for the "Historical" hydrologic sequence.

13. Water supply elements develop water in different amounts from year-to-year, and in some instances only develop water during dry years. This information is provided to illustrate a comparison between local watershed supplies, Tuolumne River supplies and other identifiable water supplies used to meet system purchase requests. Values are stated in units of average annual quantities during the simulated historical sequence.

14. Results from HH/LSM analysis of each scenario. Values represent the average annual production of each element of supply during the design drought period.

15. Simplified calculation of system deliveries during the SFPUC design drought. The value represents the application of systemwide shortages to the demand level being met with SFPUC local watershed, Tuolumne River, and other developed supplies and does not include supplies from regional water conservation, recycled water or groundwater projects. Average value may be slightly misstated (up to 3 mgd) due to metric of analysis that does not account for differences in residual storage between studies. "Nominal" Firm Yield represents the yield of each scenario after adjustment for minor residual storage differences.

16. Supplemental releases from Calaveras Reservoir for fisheries (1997 CDFG MOU) of up to 6,300 acre-feet per year and the Alameda Creek recapture facility project are tied to implementation of the Calaveras Dam Replacement project (SV-2). When the dam is replaced and capacity restored, the flow release and recapture will both occur. The release requirement is based on supplementing other occurring flows below Calaveras Reservoir, sometimes not requiring the full 6,300 acre-feet.

17. SFPUC actions are assumed to not change MID/TID diversions so as to isolate and possibly overstate the WSIP's effects on the Tuolumne River below La Grange Dam. The Districts' diversions are assumed to be constant among the scenarios to provide comparable results of WSIP-alone effects. The exception is for the Modified WSIP Alternative, in which the MID/TID diversion is reduced by the amount of SFPUC transfer.

18. Participation in the San Joaquin River Agreement is assumed. Although the agreement expires after 2010, it is assumed that a subsequent similar agreement or requirement of the Districts will occur. The HH/LSM does not explicitly model the Districts' participation in the agreement; however, their participation if modeled would result in only minor differences in results and would not change impact conclusions.

19. From HH/LSM results for modeling the SFPUC design drought period.

APPENDIX O2

2. CEQA Alternative – Modified WSIP

The Modified WSIP Alternative would implement all of the proposed WSIP facility improvement projects, but differs in that it would include measures to reduce or avoid impacts that are associated with implementing the WSIP. The measures being considered are:

- Demand reduction of an additional 10 mgd (all years) through recycled water, groundwater, and conservation projects within the wholesale customer service area
- Restricted reservoir levels at Crystal Springs Reservoir
- Bypass of an amount of flow to Alameda Creek at the Alameda Creek Diversion Dam
- Use of conserved water for the Turlock Irrigation District/Modesto Irrigation District (TID/MID) and/or other water agency transfer to the SFPUC
- Use of Pilarcitos Reservoir storage for maintenance of summer flows below Pilarcitos Dam

There would be an increase in customer demand, from 265 mgd in 2005 to 300 mgd in 2030. With the Modified WSIP Alternative, the increase would be met in part through additional water conservation, water recycling, and groundwater programs beyond those already assumed in the 2030 demand projections. A total of 10 mgd of the demand is assumed to be met through regional recycled water, groundwater, and conservation projects within the regional service area but outside of San Francisco. These projects are in addition to the 10 mgd of groundwater development, recycled water projects, and conservation in San Francisco included in the WSIP and also incorporated into this alternative. This alternative would result in an average annual net demand on the regional system of 280 mgd, compared to a net demand of 290 mgd for the WSIP setting and 265 mgd for the base setting. The net increase in water demand from the regional system would be served through additional Tuolumne River diversions, including a water transfer with the TID/MID similar to the proposed program, increased use of local watershed supplies from restoration of Calaveras Reservoir storage, water associated with restoration of Crystal Springs Reservoir, and implementation of the Westside Basin Groundwater Program.

The restricted operation of Crystal Springs Reservoir involves construction of the dam spillway at elevation 291.8 feet (modeled capacity of 21.15 billion gallons, the same as the proposed program), but operation of the reservoir with a normal maximum water surface elevation of 287.8 feet (modeled capacity of 20.28 billion gallons). The winter operation of the reservoir would provide a 2-billion-gallon storage buffer below the restricted elevation objective. This measure is intended to reduce or avoid inundation impacts of higher reservoir water surface elevations.

The Alameda Creek Diversion Dam (ACDD) bypass measure assumes the passage of up to 10 cfs or inflow, whichever is less, during the months of December through April. It is assumed that this flow to Alameda Creek below the diversion dam would be recaptured from Alameda Creek below the confluence with Calaveras Creek when the flow is utilized to meet 1997 CDFG MOU requirements. The measure is intended to reduce or avoid impacts of reducing winter and spring flows below the ACDD.

It is assumed that the transfer of water to the SFPUC would be developed through water conservation in the service areas of TID/MID and/or other water agency that would in effect reduce the TID/MID diversion of water from Don Pedro Reservoir. The measure is intended to reduce or avoid the impacts of reducing flows in the Tuolumne River below La Grange Dam.

The Pilarcitos Reservoir measure assumes the occasional use (extraction) of water from the reservoir pool below the invert of the spillway outlet at Pilarcitos Dam to maintain flow in Pilarcitos Creek below Pilarcitos Dam during July through September. The release would also maintain deliveries to Coastside CWD from the Pilarcitos Creek watershed during those months. The measure is intended to reduce or avoid the impacts associated with reduced releases to the creek during summer months.

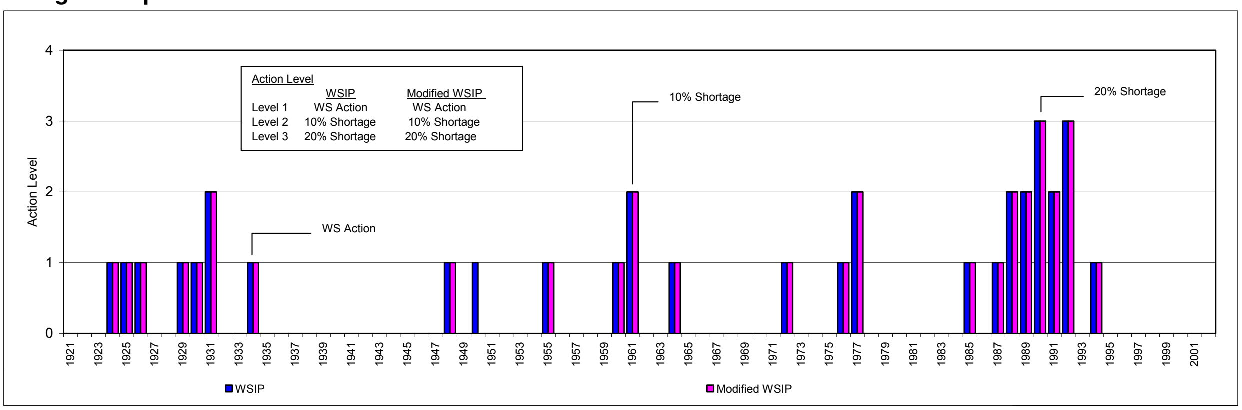
2.1 Water Deliveries and Drought Response Actions

Compared to the WSIP setting, the regional system's sources are required to serve a net 280 mgd demand (300 mgd purchase request less 10 mgd of groundwater development, recycled water projects, and conservation and 10 mgd of programs outside of San Francisco) instead of a net 290 mgd demand.

APPENDIX O2

As part of the formulation of this alternative, the water transfer from TID/MID was sized to provide the same frequency and severity of water shortages (percentage-wise) for the alternative as that occurring in the WSIP setting during the design drought, although systemwide water deliveries are a net 280 mgd in the alternative setting as compared to the WSIP setting delivery of a net 290 mgd. This objective required the water transfer to be sized at 19,600 acre-feet per year compared to 29,350 acre-feet per year in the WSIP setting. Factors that change the size of the transfer include the net demand, the change in maximum storage capacity at Crystal Springs Reservoir, and reservoir evaporation. The most substantial factors are net demand and the storage at Crystal Springs Reservoir. With a water supply formulated about comparable to that provided for the WSIP setting (only proportionately smaller for a lesser demand), the implementation of rationing and the severity of rationing from the SFPUC system during drought periods would be the same. Table 1-1 illustrates the comparison of the drought response actions for the proposed program and the alternative. Figure 2.1-1 illustrates the occurrence of drought response actions for the simulated 82-year historical period (1921-2002) for the WSIP and Modified WSIP settings.

Figure 2.1-1
Drought Response Actions – WSIP and Modified WSIP



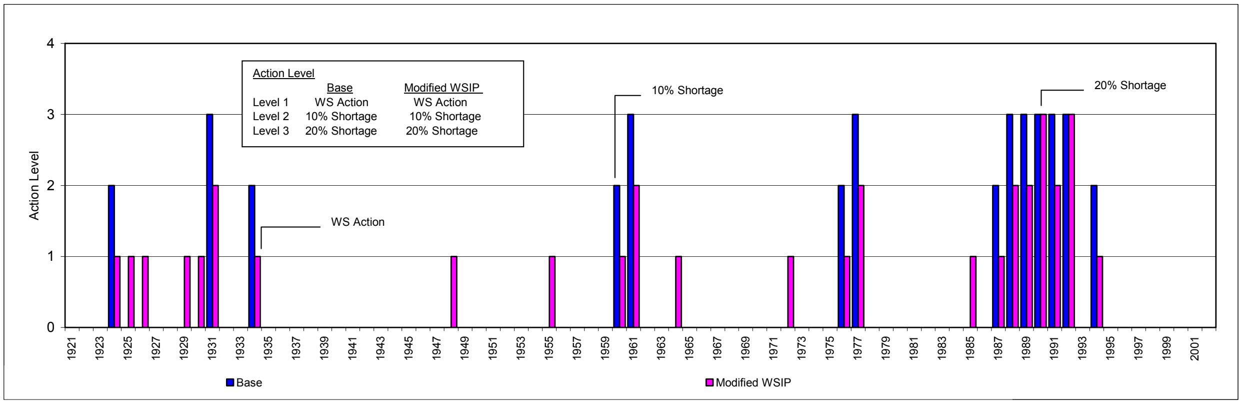
In Figure 2.1-1, years with bars showing a “1” or greater level of action indicate periods when a supplemental water supply action is initiated. In both settings, the water supply action is the use of the Westside Basin Groundwater Program to supplement SFPUC water deliveries. Also occurring in both settings is the water transfer supplemental supply from TID/MID. An action level greater than “1” indicates the imposition of delivery shortages (rationing) for SFPUC customers. SFPUC customers would experience the same frequency and severity of shortages (percentage-wise) during the design drought in both settings, and the frequency of shortage in other drought periods would the same. The triggering of the Westside Basin Groundwater Program supplemental supply occurred in one less year in comparison to the proposed program.

The same form of information is shown in Figure 2.1-2 for the comparison between the alternative and the base settings. There is not a level 1 action in the base setting. Without supplemental resources, the existing system only has delivery shortage measures available to cope with drought. In the base setting, the shortage measure is imposed during level 2 (10 percent) and level 3 (20 percent). These percentages of shortage are applied to both the alternative and the base settings for these action levels. During this simulation period, rationing does not need to exceed 20 percent in either setting; however, in the alternative setting, the occurrence of additional water supplies lessens the frequency and severity of water delivery shortages.

Not illustrated in Figure 2.1-2 but shown in Table 1-1 are the delivery shortages anticipated during the entire SFPUC design drought. During the design drought, the base setting does not have a viable operation without exceeding the 20 percent shortage level. The base setting exceeds the 20 percent shortage level (requires 25 percent rationing) during the last 18 months of the design drought. The alternative would viably provide deliveries without exceeding the 20 percent shortage level.

APPENDIX O2

Figure 2.1-2
Drought Response Actions – Base and Modified WSIP



The difference in water deliveries between the proposed program and the alternative is shown chronologically for the 82-year simulation in Table 2.1-1. There would be less water delivered to the region by the SFPUC in all years, a result of serving a lesser net demand of 280 mgd instead of 290 mgd.

Comparing the alternative setting to the base setting, Table 2.1-2 illustrates the difference in water deliveries between the two settings. The increases in deliveries under the alternative setting occur due to the increase in net demand served by the regional system (280 mgd instead of 265 mgd) and an improvement in water delivery reliability that reduces the severity of water shortages during several drought periods.

2.2 Diversions from the Tuolumne River

The metric for illustrating the SFPUC diversions from the Tuolumne River Basin (Tuolumne) is the flow through the San Joaquin Pipeline (SJPL). Inherent in this alternative is a net water demand that is less than the demand served by the proposed program but greater than the demand served under the base condition. Table 2.2-1 illustrates the difference in diversions to the SJPL between the proposed program and the alternative settings. In both settings, the conveyance capacity of the SJPL is increased compared to the base setting. During the summer, the SJPL would essentially operate at the same maximum rate in both the alternative and WSIP settings to minimize the drawdown of Bay Area reservoir storage. A few exceptions occur during the summer due to differences in operations for the net demand served. Overall, compared to the WSIP setting, the alternative setting would divert less water from the Tuolumne.

Table 2.2-2 illustrates the difference in diversions to the SJPL between the alternative and base settings. Evident in the operation is the increase in summer diversions associated with an increase in the conveyance capacity of the SJPL. As described above, with the increase in SJPL conveyance capacity, summer diversions would increase to retain storage in the Bay Area reservoirs. With the increase in summer diversions to the SJPL and the retention of storage in the Bay Area reservoirs, there would at times be reduced diversions during the late summer and fall as less Tuolumne water would be needed to replenish the Bay Area reservoirs. The differences in December diversions are largely the result of maintenance occurring in the alternative setting (lessening available conveyance capacity) that does not occur in the base setting. The increased diversions during the winter and spring result from the need to replenish Bay Area reservoir storage after the maintenance and then top off Bay Area reservoir storage prior to summer. There would be an overall increase in average annual diversions to the SJPL in the alternative setting associated with the increase in net demand and the improvement in water delivery reliability.

Table 2.2-3 illustrates the average monthly diversions through the SJPL by year type for the 82-year simulation for the proposed program and the alternative settings and the difference between the two settings. Table 2.2-4 shows the same information for the alternative and base settings.

2.3 Hetch Hetchy Reservoir and Releases

Compared to the WSIP setting, the alternative setting draws less water from the Tuolumne due to the lesser demand. This circumstance leads to less draw from Hetch Hetchy Reservoir in the alternative setting in all years. Figure 2.3-1 illustrates a chronological trace of the simulation of Hetch Hetchy Reservoir storage and stream releases. Shown in Figure 2.3-1 are the results for the WSIP, Modified WSIP, and base settings. Supplementing the Figure 2.3-1 representation of Hetch Hetchy Reservoir storage are Table 2.3-1, Hetch Hetchy Reservoir Storage (Modified WSIP); Table 2.3-2, Hetch Hetchy Reservoir Storage (WSIP); and Table 2.3-3, Difference in Hetch Hetchy Reservoir Storage (Modified WSIP minus WSIP). Table 2.3-4 is provided to illustrate the difference in Hetch Hetchy Reservoir storage between the base and alternative settings.

Table 2.3-3 shows that, by the end of summer, storage in Hetch Hetchy Reservoir associated with the alternative setting would at times (about 20 percent of the years) be greater than the storage in the WSIP setting, albeit typically less than 5,000 acre-feet more in two-thirds of those years. In about one-third of the years, storage would be greater by 5,000 acre-feet or more. The relatively minor increases in storage are attributable to years when summer diversions would be the same in both settings (SJPL operating at maximum capacity) but less water would be diverted in the fall due to the lesser water demand. The larger increases in storage are associated with drought periods during which the differences in underlying demand and water delivery shortages between the WSIP and alternative settings are greater.

Through the fall and winter, storage in Hetch Hetchy Reservoir would be the same or higher under the alternative setting as compared to the WSIP setting. Hetch Hetchy Reservoir would fill by the end of May or June during approximately 80 percent of the years, which would prevent any difference in storage from affecting the next summer's reservoir storage. Figure 2.3-2 illustrates the difference in reservoir storage, averaged by year type, between the alternative and the WSIP settings. Also shown is the average difference in storage for the two settings during the 82-year simulation.

Table 2.3-4 illustrates the difference in Hetch Hetchy Reservoir storage between the alternative and base settings. Immediately after filling Hetch Hetchy Reservoir (May or June, and then continuing through July), there would only be occasional differences in storage at the reservoir, typically a decrease of less than 10,000 acre-feet. This is indicative of the same amount of water being passed through the reservoir regardless of the size of the conveyance capacity of the SJPL. Water not diverted to the SJPL would return to the Tuolumne River and flow to Don Pedro Reservoir. In the late summer and early fall, there would consistently be a slight difference (lower) in storage levels between the two settings, as additional diversions to the SJPL would retain Bay Area reservoir storage and serve a slightly greater demand. Some of this additional Hetch Hetchy Reservoir storage depletion would be ameliorated later in the fall and into winter as SJPL diversions are reduced due to less Bay Area reservoir replenishment needs and conveyance system maintenance. Average storage is incidentally about the same in November and December for the alternative and base settings due to the assumed systemwide maintenance that would occur in the alternative setting but not in the base setting. After December, the storage gain occurring in the alternative setting would again be affected as replenishment of Bay Area reservoir storage resumes. In non-wet years, there is a difference in storage between the alternative and base settings; the alternative setting results in a lower storage in the reservoir by the end of April. Figure 2.3-3 illustrates the difference in reservoir storage, averaged by year type, between the alternative and base settings. Also shown is the average difference in storage for the two settings during the 82-year simulation. Figure 2.3-4 illustrates the average monthly storage in Hetch Hetchy Reservoir for the 82-year simulation, and the range in storage for each month for the alternative and base settings.

The difference in storage in Hetch Hetchy Reservoir attributed to the diversion effects of the alternative would manifest in differences in releases from O'Shaughnessy Dam to the stream. A different amount of available reservoir space in the winter and spring due to the alternative would lead to a different ability to regulate inflow, thus potentially changing the amount of water released to the stream that is in excess of minimum release requirements. Figure 2.3-1 illustrates the stream release from O'Shaughnessy Dam for the WSIP, alternative, and base settings. Table 2.3-5 illustrates the difference in stream releases between the alternative and WSIP settings. Compared to the WSIP setting, the alternative exhibits an incrementally greater stream release, predominately during May or June, which is reflective of the months when releases to the stream are made in excess of minimum release requirements in anticipation of filling the reservoir. The few exceptions to this circumstance, during which incremental reductions in releases to the stream occur, are considered anomalous within the modeling and are simply the result of shifting releases from one month to the next. The increase in releases is the result of a less-depleted reservoir to replenish, which is the result of lesser SFPUC demands (and Tuolumne River diversions) between the settings.

Table 2.3-6 illustrates the difference in stream releases between the alternative and base settings. In this comparison, releases would be predominately less than depicted for the base setting, and these differences would typically occur during May or June. Generally, Hetch Hetchy Reservoir storage would be slightly lower during non-wet years, leading to a reduction in stream releases during non-wet years if a release occurs. The few instances of stream flow increases are a result of a coincidence of several operational parameters affecting the release of water from the reservoir, including systemwide water demands, conveyance capacity and maintenance assumptions, and the watershed's hydrology.

Table 2.3-5 illustrates the difference in stream releases between the alternative and WSIP settings, expressed in terms of a monthly volume (acre-feet) of flow. Table 2.3-7 illustrates the same information and the average monthly stream releases for the alternative and WSIP settings, expressed in average monthly flow (cfs). Table 2.3-5 shows an increase in monthly flow below O'Shaughnessy Dam of up to approximately 20,000 acre-feet. Considering the manner in which releases are determined and made to the stream, it is not always meaningful to quantify the effect of these changes in terms of

average monthly flow (cfs).[1] When comparing the alternative to the WSIP setting, a change in the volume of release from O'Shaughnessy Dam to the stream would likely result in the release being delayed or initiated earlier by a matter of days. Typical springtime releases, when initiated, amount to a release of up to 3,000 cfs (approximately 6,000 acre-feet over the span of a day). Using the assumption that a change in release volume equates to a delay or an earlier initiation of releasing 6,000 acre-feet per day means that the difference in stream release between the alternative and WSIP would be up to an added three days of release. Normally, this change in release would not affect the peak stream release rate during a year. Table 2.3-8 illustrates the average monthly stream release for the alternative and base settings, and the differences, expressed in average monthly flow (cfs). Table 2.3-6 illustrates that the difference in monthly flow below O'Shaughnessy Dam between the alternative and base settings could range from an increase of approximately 18,000 acre-feet to a decrease of approximately 39,000 acre-feet. Using the same metric as described above to estimate the delay or addition in the number days of release to the stream, the alternative could lead to an effect ranging from an increase of three days of release to a decrease of up to seven days compared to the base setting.

APPENDIX O2

2.4 Lake Lloyd and Lake Eleanor

Compared to the operation of the WSIP, the operation of Lake Lloyd and Lake Eleanor are simulated to be only slightly different for the alternative. Figure 2.4-1 illustrates a chronological trace of the simulation of Lake Lloyd storage and stream releases. Shown in Figure 2.4-1 are the results for the WSIP, alternative, and base settings. The operation resulting from the alternative is essentially the same as the WSIP setting, including during drought. The level of delivery between the alternative and base settings is larger during the 1987-1992 drought, and water delivery reliability has been improved in the alternative setting; as a result, the drawdown of Lake Lloyd during this period looks similar to that in the WSIP setting. Although there is less water delivered during this period in the alternative setting compared to the WSIP setting, more water is delivered in the alternative setting than in the base setting. The additional draw of water reduced the amount of water released from Hetch Hetchy Reservoir to Don Pedro Reservoir in the alternative setting, which, in order to satisfy TID/MID entitlements to inflow, was met with additional releases from Lake Lloyd, similar to the WSIP setting. The additional release from Lake Lloyd associated with the alternative appears to be approximately the same as in the WSIP setting in this instance, which is partially a factor of modeling discretion in that the HH/LSM makes release decisions in the form of block amounts of releases. Additional refinement of modeling assumptions would likely produce a result that places Lake Lloyd storage during this drought period between the base setting and WSIP setting results. Otherwise, the results for Lake Lloyd storage are essentially the same between the WSIP and alternative settings.

Figure 2.4-2 illustrates the almost identical operation of Lake Eleanor for the alternative and WSIP settings. Also shown in Figure 2.4-2 is the operation for the base setting. Any difference in the Lake Eleanor operation would be caused by a small change in operation at Lake Lloyd that would affect the operation of the Cherry-Eleanor Tunnel between the two watersheds. Any difference that occurs in the simulations is more likely the result of modeling discretion as opposed to any substantive difference in operation.

Supplementing the Figure 2.4-1 representation of Lake Lloyd stream releases is Table 2.4-1, which illustrates releases for the alternative and WSIP settings, and the difference in releases between the two settings. Table 2.4-2 provides the same form of information for the alternative and base settings. With essentially no change in reservoir operations, stream releases will not be different.

2.5 Don Pedro Reservoir and La Grange Releases

A change in Don Pedro Reservoir operation is caused by changes in inflow to the reservoir and the releases from the reservoir. The changes in inflow to the reservoir are the result of net changes within the operation of the upstream SFPUC facilities described previously, and other changes in SFPUC operations associated with diversions to the Holm, Kirkwood, and Moccasin Powerhouses. Figure 2.5-1 illustrates a chronological trace of the simulation of Don Pedro Reservoir storage and Tuolumne River stream releases from La Grange Dam. Shown in Figure 2.5-1 are the results for the WSIP, alternative, and base settings. Supplementing the Figure 2.5-1 representation of Don Pedro Reservoir storage are Table 2.5-1, Don Pedro Reservoir Storage (Modified WSIP); Table 2.5-2, Don Pedro Reservoir Storage (WSIP); and Table 2.5-3, Difference in Don Pedro Reservoir Storage (Modified WSIP minus WSIP). Table 2.5-4 is provided to illustrate the difference in Don Pedro Reservoir storage between the base and alternative settings.

Table 2.5-3 shows that, throughout many years, the storage in Don Pedro Reservoir associated with the alternative setting would differ from the storage in the WSIP setting, and this difference would almost always be more storage. Table 2.5-4 illustrates that Don Pedro Reservoir storage for the alternative is close to the storage depicted for the base setting; storage is either higher or lower, but is typically higher than in the base setting. Compared to the WSIP setting, the differences in storage are indicative of the increase in inflow to Don Pedro Reservoir that is due to lesser SFPUC demands and SJPL diversions in the alternative setting. The increases in storage are also due to a decrease in TID/MID canal diversions from the assumption that conserved water would be developed for the SFPUC transfer. Compared to the base setting, the alternative would result in typically less inflow to Don Pedro Reservoir during non-wet years and particularly during drought periods when more water is diverted

to the SJPL in the alternative setting. Less inflow leads to less reservoir storage. Figure 2.5-1 illustrates that during drought sequences, a reduction to inflow to Don Pedro Reservoir can accumulate from year to year, particularly in the comparison of the WSIP and base settings. Compared to the base setting, storage in Don Pedro Reservoir in the alternative setting would be nearly the same. Figure 2.5-2 illustrates the difference in reservoir storage averaged by year type for the alternative and WSIP settings. Also shown is the average difference in storage for the two settings during the 82-year simulation. Figure 2.5-3 illustrates the same information for the alternative and base settings.

Figure 2.5-2

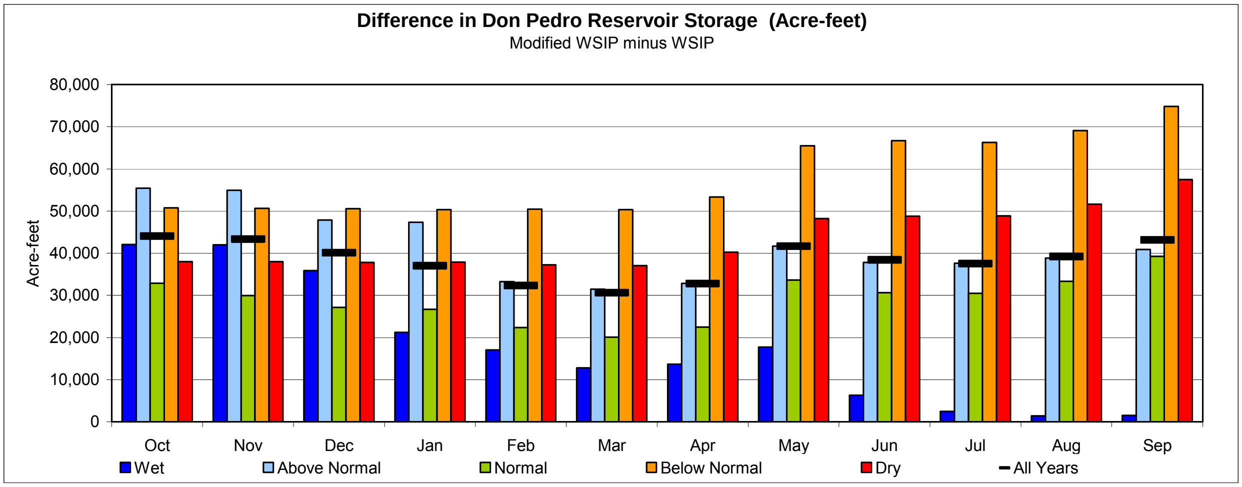

Figure 2.5-3

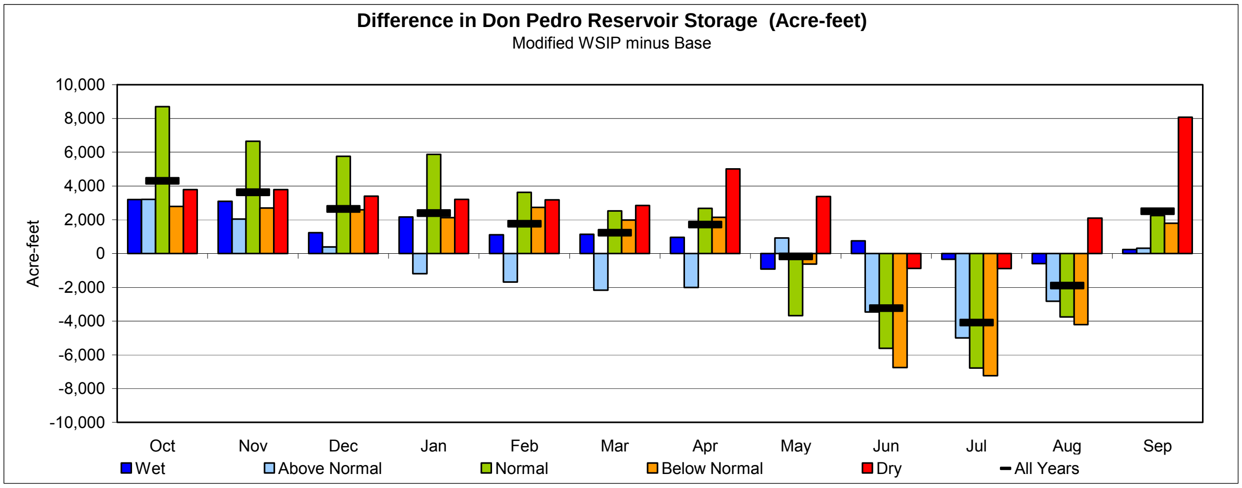

Figure 2.5-4 illustrates the average monthly storage in Don Pedro Reservoir for the 82-year simulation, and the range in storage for each month for the alternative and base settings.

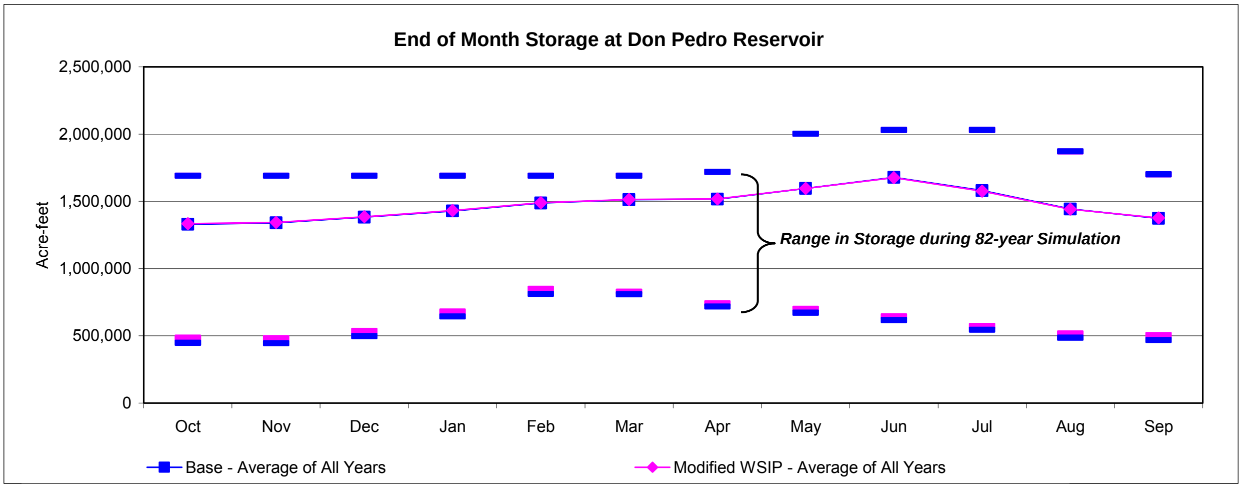
The simulation shows that the occasional large storage depletions in Don Pedro Reservoir associated with the WSIP would be largely ameliorated by the use of conserved water for the transfer. In the alternative setting, the SJPL diverts an average of 17,000 acre-feet more than in the base setting, and the transfer is an annual average of 19,600 acre-feet for design drought yield purposes. It is assumed that the conservation of water for the transfer is also 19,600 acre-feet every year to satisfy the SFPUC's need for yield during the design drought sequence. Because the conserved water transfer (occurring each year) would be greater than the SJPL/inflow effect, Don Pedro Reservoir storage, and the La Grange release to the Tuolumne River as described below, could be slightly larger at times than in the base setting. In a few other instances, Don Pedro Reservoir storage and La Grange releases could be lower. The development and transfer of conserved water is not a perfect match (total elimination of effect) each year due to several factors, particularly the fact that the year-to-year and average numbers do not always coincide.

Figure 2.5-4



Sometimes a portion of the conserved water would be developed prior to an ensuing reservoir spill and could not be used to reduce an accumulating inflow deficit that occurred subsequent to the spill. Also, the additional SJPL diversion and its effect on Don Pedro Reservoir inflow would not occur at a constant year-to-year rate; sometimes more than the average effect, and sometimes less than the average effect, would occur. This circumstance could lead to a larger storage deficit in a year than the amount of water conserved in a year, and vise versa. Depending on the coincidence of the hydrologic sequence of Don Pedro Reservoir replenishment and the running accumulation of the inflow effect, the storage deficit might not be totally ameliorated during all hydrologic sequences.

The difference in storage in Don Pedro Reservoir attributed to the upstream effects of the alternative and the countering reduction in the TID/MID canal diversions would manifest in differences in releases from La Grange Dam to the stream. A different amount of available reservoir space in the winter and spring due to the alternative would lead to a different ability to regulate inflow, thus potentially changing the amount of water released to the stream that is in excess of minimum release requirements. During periods when inflow or canal diversions differ and Don Pedro Reservoir is at maximum capacity within the flood control storage limitation, a change in inflow or canal diversions directly manifests as a change in releases from La Grange Dam (a change of either more or less flow). Figure 2.5-1 illustrates the stream releases from La Grange Dam for the WSIP, alternative, and base settings.

Table 2.5-5 illustrates the difference in stream releases between the alternative and WSIP settings. Compared to the WSIP setting, the alternative exhibits an incrementally larger stream release, predominately during some months of the early winter through June period, which is reflective of the months when releases to the stream are made in excess of minimum release requirements due to flood control or in anticipation of filling the reservoir. Table 2.5-6 shows the same information for the alternative and WSIP settings, arranged by ranking the years in descending order of the San Joaquin River Index (an index indicating the wetness of the Tuolumne River Basin and the San Joaquin River Basin). The table illustrates the finding that differences in releases to the Tuolumne River from La Grange Dam occur only when there are releases in excess of minimum FERC flow requirements. This circumstance typically occurs only in above-normal and wet years, and predominately during early winter through June. During late summer of above-normal and wet years (August and September) there may also be releases in excess of minimum FERC flow requirements. These releases are associated with the drawdown of Don Pedro Reservoir during antecedent wetter years in anticipation of fall-time flood control objectives. During other year types and typically during the summer and fall, releases would be maintained at minimum FERC flow requirements regardless of the setting. Compared to the WSIP setting, the large potential reduction in flow following an extended drought period is reduced with the alternative, since the amount of water delivered by the SFPUC during these periods is somewhat less than that delivered in the WSIP setting, and the water for additional deliveries is derived from conserved water in Don Pedro Reservoir.

As described above concerning Don Pedro Reservoir inflow, releases, and storage, compared to the base setting the alternative setting would lead to a mixed effect on La Grange releases. Table 2.5-7 illustrates the difference in stream releases between the alternative and base settings. Table 2.5-8 shows the same information ranked in descending order of the San Joaquin River Index. Overall, releases below La Grange Dam are very similar between the alternative and base settings. This circumstance is the intended result of the mitigation measure under this alternative to use conserved water to offset the Don Pedro Reservoir inflow effect of the SFPUC's additional diversion of water from the Tuolumne River. As seen in some months, such as August and September, there are occasional increases in La Grange releases. These are instances when developing conserved water every year sometimes only adds to the water that would be released in excess of FERC requirements during a drawdown of storage prior to the fall flood control level at Don Pedro. Also, some positive values occur when early-season conserved water only adds to Don Pedro spills prior to filling.

In year-to-year operations, the conserved water could be adjusted if it would merely turn into an unneeded spill. However, outside of flood events, additional flow during the summer as a result of the conserved could be welcomed. For purposes of this analysis, the conserved water is assumed to be developed each year. However, it should be noted that the additional flow that occurs due to the conserved water was not explicitly patterned for any purpose except to draw Don Pedro Reservoir down to flood control objectives.

Table 2.5-5 and Table 2.5-7 illustrate the difference in stream releases among the alternative, WSIP, and base settings, expressed in terms of a monthly volume (acre-feet) of flow. Table 2.5-9 presents the same information and the average monthly stream releases for the alternative and WSIP settings, expressed in total monthly flow (acre-feet), and Table 2.5-10 shows the same information for the alternative and base settings. For the comparison of the alternative to the WSIP setting, the difference in monthly flow below La Grange Dam could range from an increase of approximately 212,000 acre-feet to a decrease of approximately 6,000 acre-feet. Considering the manner in which releases are determined and made to the stream, it is not always meaningful to quantify the effect of these changes in terms of average monthly flow (cfs). Similar to the operation of releases below O'Shaughnessy Dam, a change in the volume of release from La Grange Dam to the stream would likely delay or accelerate the initiation of the release by a matter of days. Using the assumption that a change in release volume equates to a delay or acceleration of releasing 6,000 acre-feet per day means that the difference in stream release from La Grange Dam between the alternative and WSIP would be an additional day of delay in releases or up to almost an added month of releases. Normally, a change in release would not affect the peak stream release rate during a year. Compared to the base setting, the alternative's effect on stream flow ranges from a reduction in releases (a potential delay in release of five days) to an increase in releases (a potential additional five days of release). In either direction, the maximum difference in La Grange releases between the alternative and base settings was reduced to about 30,000 acre-feet as the result of the conserved water measure.

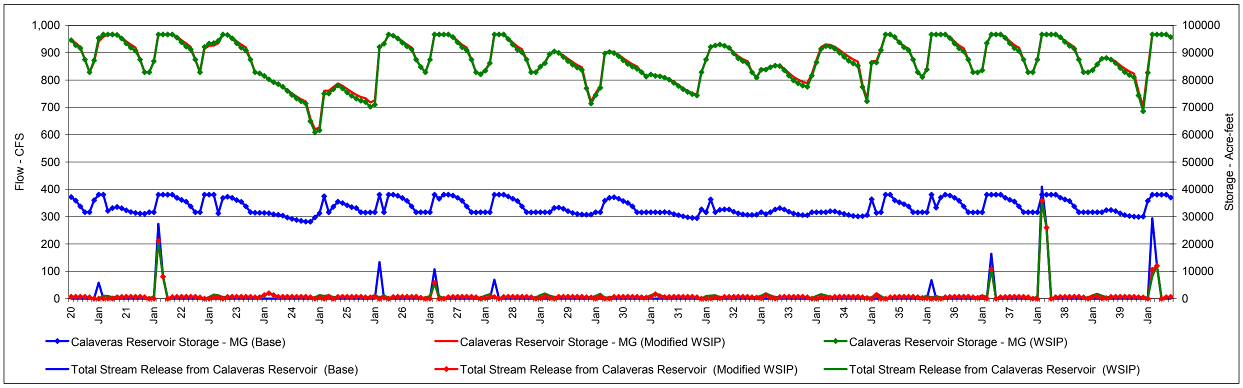
2.6 Calaveras and San Antonio Reservoirs, Alameda Creek, and Downstream

Compared to the WSIP setting, the operation of Calaveras Reservoir in the alternative setting is almost identical. Figure 2.6-1 illustrates a chronological trace of the simulation of Calaveras Reservoir storage and stream releases from Calaveras Dam. Shown in Figure 2.6-1 are the results for the WSIP, alternative, and base settings. In recognition of the different levels of systemwide deliveries served in each setting, the near identical operation of Calaveras Reservoir resulting from the two settings is an indication that Calaveras Reservoir operations are mostly influenced by the principles that manage local watershed production. The slight differences in reservoir operation are the result of modeling assumptions that balance reservoir storage among SFPUC reservoirs and the selection of the monthly SJPL conveyance rate. It is anticipated that the difference in Calaveras Reservoir operation during actual operations would be minimal, if any difference occurred at all. The difference in storage between the alternative and WSIP settings and the base setting is due to the restoration of the operational capacity of Calaveras Reservoir. Under both the alternative and WSIP settings, the full capacity of Calaveras Reservoir would be available, and a greater range in storage operation would occur. Figure 2.6-2 illustrates the average monthly storage in Calaveras Reservoir for the 82-year simulation, and the range in storage for each month for the alternative and base settings.

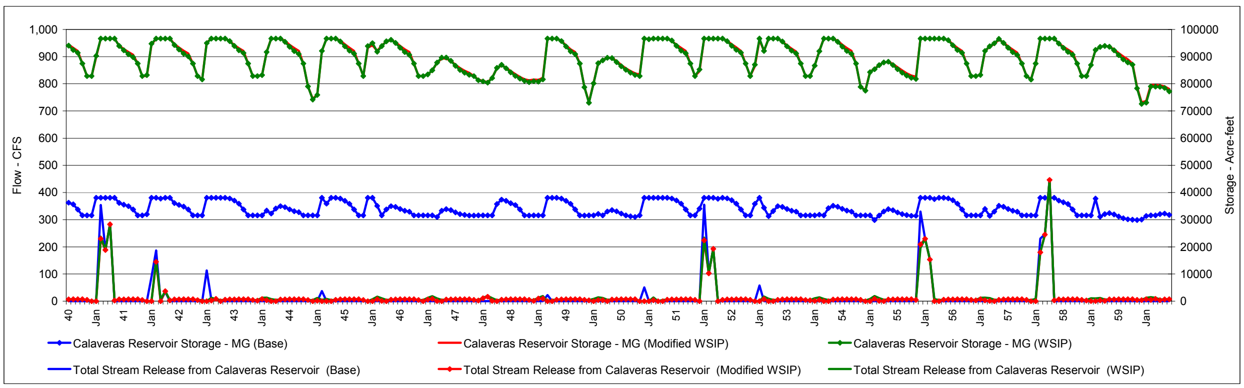
APPENDIX O2

Figure 2.6-1
Calaveras Reservoir Storage and Stream Release

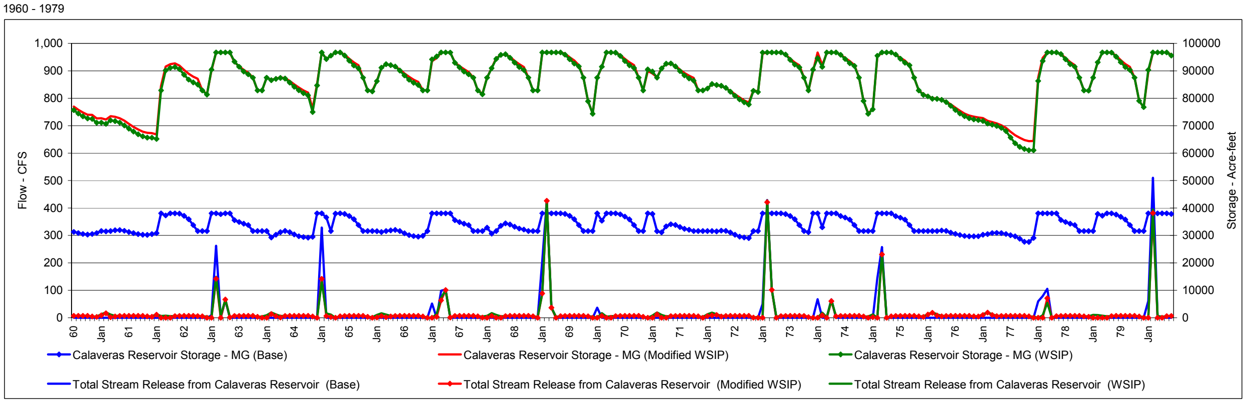
1920 - 1939



1940 - 1959



1960 - 1979



1980 - 2002

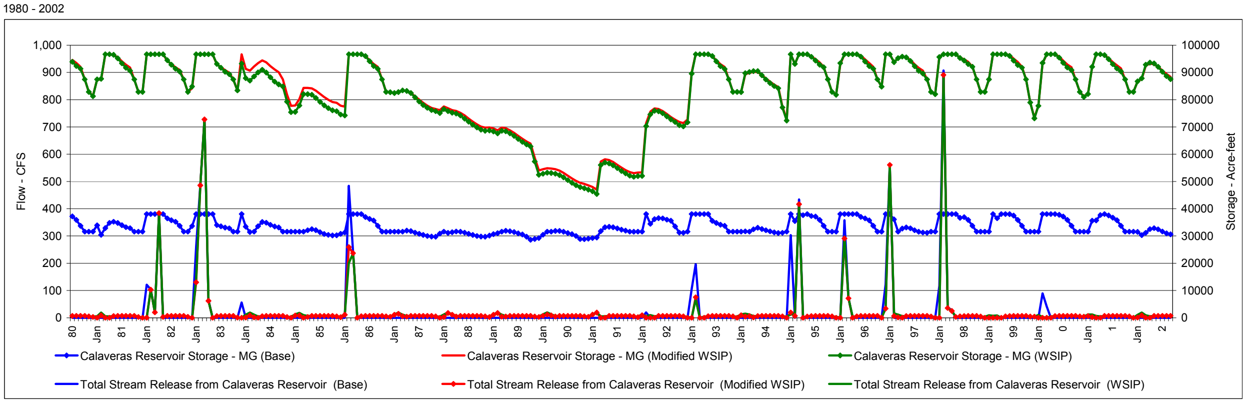


Figure 2.6-2

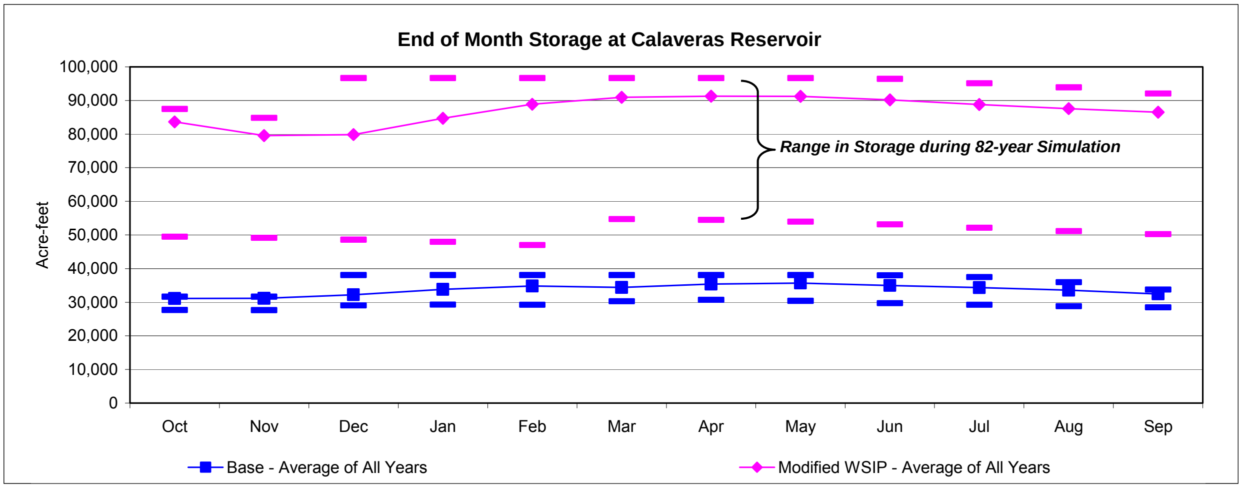

There would be almost identical spills from Calaveras Reservoir for the alternative and WSIP settings. Both the alternative and WSIP settings have fishery releases (1997 CDFG MOU) that are not included in the base setting. Table 2.6-1 illustrates the difference in releases to Calaveras Creek between the alternative and WSIP settings. The difference in flow (for the reach below Calaveras Reservoir to the confluence with Alameda Creek) during December through April is due to the flow bypass measure at ACDD that is associated with the Modified WSIP setting. The reductions in flow in this reach of stream are an indication that bypass flow is being provided at the diversion dam and is subsequently used to contribute to the 1997 MOU flow requirement at the confluence. The bypass flow does not exist in the WSIP setting, and additional releases would be required from Calaveras Reservoir to meet the 1997 MOU flow requirement. Supplementing the Figure 2.6-1 representation of Calaveras Dam stream releases and Table 2.6-1 is Table 2.6-2, which illustrates releases for the alternative and WSIP settings, and the difference in releases between the two. Table 2.6-3 provides the same form of information for the alternative and base settings. The notable difference in releases between the alternative and base settings is the addition of the required flows to satisfy the 1997 MOU and the reduction of stream releases during wetter-year, wetter-season flows due to the restoration of Calaveras Reservoir operational capacity.

The bypass flow measure at the ACDD is modeled as a release at the diversion dam of 10 cfs or inflow to the diversion dam, whichever is less, for the months December through April. Table 2.6-4 illustrates the flow past the ACDD for the alternative setting, which includes the bypass measure. Table 2.6-5 illustrates the flow for the WSIP setting, and Table 2.6-6 illustrates the difference in flow below the ACDD between the alternative and WSIP settings. As seen in Table 2.6-4, flow past the diversion dam occurs regularly during the December through April period, its magnitude either as an explicit bypass of up to 10 cfs (approximately 600 acre-feet per month), or more during rain-runoff events when either Calaveras Reservoir is not receiving water from Alameda Creek or the runoff at the diversion dam exceeds the diversion tunnel capacity. Table 2.6-6 illustrates the difference in flow below the diversion dam between the two settings. The positive values (up to 10 cfs) indicate the measure's passage of flow that would otherwise not occur in the WSIP setting. The few exceptions of reduced flow indicate periods when the alternative setting would divert more water to Calaveras Reservoir from the diversion dam; however, review of the remaining flow below the diversion dam (Table 2.6-4) shows that it would still be in excess of the minimum bypass flow.

Table 2.6-7 illustrates the difference in flow below the ACDD between the alternative and base settings. The seasonal increase in flow past the diversion dam in the alternative setting is again apparent. The reductions in flow below the diversion dam are due to the additional diversions to Calaveras Reservoir resulting from the restoration of reservoir operating capacity. Table 2.6-8 and Table 2.6-9 illustrate the flow past the ACDD, comparing the alternative, WSIP, and base settings by year type and the average of all years.

Comparing the alternative and WSIP settings, differences in releases from Calaveras Dam to the stream and differences in spills and bypass flows at the ACDD result in differences in flow below the Alameda Creek and Calaveras Creek confluence between the settings. Table 2.6-10 illustrates the flow below the confluence for the alternative and WSIP settings. The flow would be generally the same, with slightly additional flow occurring during December and April due to the bypass flows. Fishery releases for the 1997 MOU are assumed in both of the settings. Table 2.6-11 provides the same form of information for the alternative and base settings. The notable differences between the alternative and base settings (comparable to the differences between the WSIP and base settings) are the addition of required stream flows for the 1997 MOU and the reduction of wetter-year, wet-season flows due to the restoration of Calaveras Reservoir storage.

A flow recapture facility in Alameda Creek below Calaveras Reservoir is incorporated in the alternative and WSIP settings. This facility is assumed to recapture flows explicitly released for the 1997 MOU. The effect of the recapture would be a reduction in the flow below the confluence of Alameda and Calaveras Creeks, but only to the extent that releases were explicitly made for the 1997 MOU. Flows below this diversion have been estimated and noted as the flow above the Alameda Creek and San Antonio Creek confluence. Table 2.6-12 illustrates the flow at this location for the alternative and WSIP settings. The flows identified at this location are indicative of flow occurring below the confluence of Alameda and Calaveras Creeks (described above) with the addition of estimated stream accretions between the Alameda and Calaveras Creek confluence and the Alameda and San Antonio Creek confluence, less the water assumed to be recaptured (diverted) by the SFPUC from the creek. The flow changes at this location for the comparison of the WSIP and alternative settings are considered insubstantial and may not occur. The differences during the December through April period of wetter years indicate that too much of the spills/releases past the diversion dam were counted as 1997 MOU releases and were subsequently recaptured. The modeled accounting tends to overstate the amount of water allowed to be recaptured. A more precise accounting method would tend to minimize the differences between the alternative and WSIP settings. Table 2.6-13 provides the same form of information for the alternative and base settings.

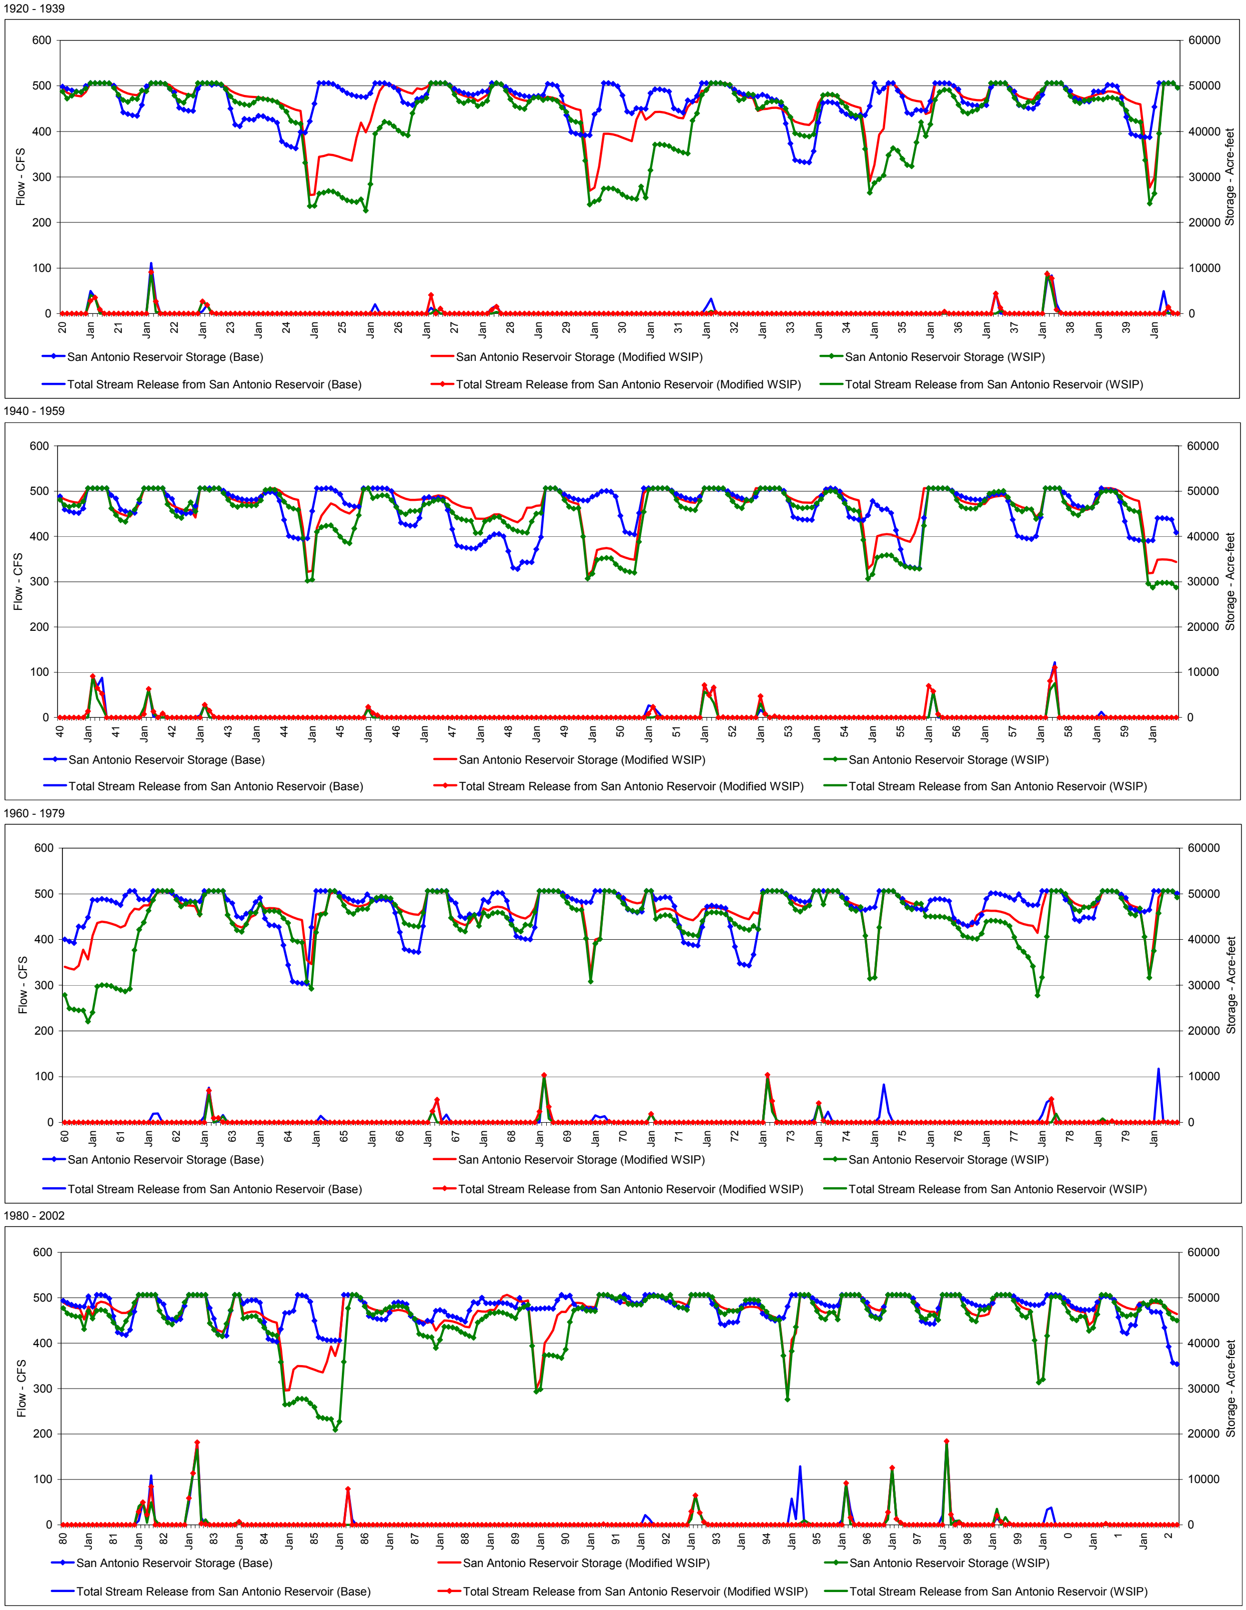
Compared to the WSIP setting, the alternative's San Antonio Reservoir operation would draw less from storage on an annual basis, particularly during cyclic maintenance. Figure 2.6-3 illustrates a chronological trace of the simulation of San Antonio Reservoir storage and stream releases from San Antonio Dam. Shown in Figure 2.6-3 are the results for the WSIP, alternative, and base settings. The difference in San Antonio Reservoir storage between the alternative and WSIP settings is mostly caused by the lesser demand of the alternative. Considering that Calaveras Reservoir storage is essentially the same between the settings, the difference in San Antonio Reservoir storage is indicative of the operational strategy to affect storage in San Antonio Reservoir more than storage in the other SFPUC Bay Area reservoirs. San Antonio Reservoir would retain more storage in the alternative setting compared to the WSIP setting.

The difference in storage between the alternative and WSIP settings and the base setting is due to the restoration of the operational capacity of Calaveras Reservoir. In the base setting, the limited operating storage capacity at Calaveras Reservoir leads to a different operation at San Antonio Reservoir, one that retains relatively more stored water for system demands when the draw from Calaveras Reservoir is constrained due to limited storage. There is also a notable difference in storage operation between the alternative and WSIP settings and the base setting due to assumed maintenance. Assumed systematic maintenance of Hetch Hetchy conveyance facilities constrains diversions to the Bay Area from Hetch Hetchy every year, and particularly during every fifth year, in the WSIP and alternative settings.

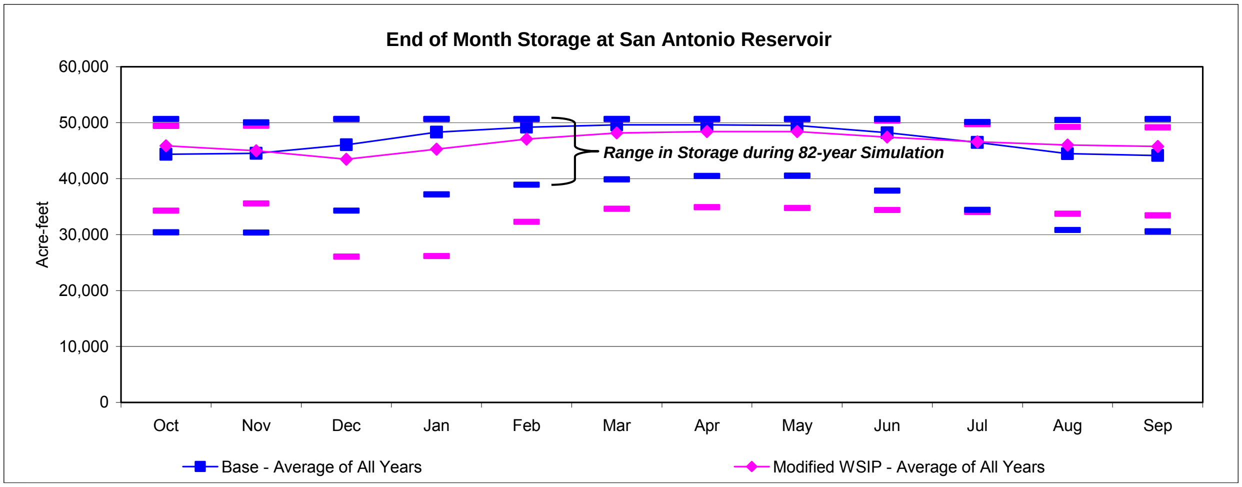
APPENDIX O2

Figure 2.6-3
San Antonio Reservoir Storage and Stream Release



The reduction in diversions from Hetch Hetchy during these periods is accommodated in the system by drawing additional water from the Bay Area reservoirs. The proportionate share of this operation is evident in the tracing of San Antonio Reservoir storage for the alternative and WSIP settings. Figure 2.6-4 illustrates the average monthly storage in San Antonio Reservoir for the 82-year simulation, and the range in storage for each month for the alternative and base settings. Compared to the base setting, the alternative would draw less storage from San Antonio Reservoir during many years, typically retaining a fuller reservoir, but would draw more storage during the every-fifth-year maintenance cycle.

Figure 2.6-4



There is very little anticipated change in stream releases below San Antonio Reservoir between the alternative and WSIP settings. Table 2.6-14 illustrates the modeled releases to San Antonio Creek from San Antonio Reservoir for the two settings and the differences for the average release during a year type. With a fuller reservoir operation at times, as seen in Figure 2.6-3, it is expected that there would be a decrease in the ability to regulate reservoir inflow and avoid stream releases. Given the sometimes rigid constraints within the modeling assumptions, the model will overestimate the frequency and magnitude of stream releases from San Antonio Reservoir under any of the investigated settings. The flexibility that occurs in actual operations would likely avoid most of the releases represented by the model. The modeled stream releases from San Antonio Reservoir and the difference between releases for the alternative and base settings are shown in Table 2.6-15. The differences between the two settings reflect a general decrease in modeled releases in the alternative setting. This modeled circumstance reflects the different resulting storage operation between the two settings, as seen in Figure 2.6-3. In most instances, the alternative setting storage at San Antonio Reservoir during a period would be equal to or lower than that projected for the base setting during the same period. This circumstance could lead to an occasionally greater modeled release for the base setting, which is reflected in the results. As described above, the model will overestimate the frequency and magnitude of releases from San Antonio Reservoir, and the actual releases from the reservoir in any setting and the difference between settings are expected to be minor.

Flow below the confluence of Alameda and San Antonio Creeks is influenced by releases from San Antonio Creek and flow arriving at the location from Alameda Creek, which includes upstream impairment by SFPUC operations and facilities. Table 2.6-16 illustrates the flow below the confluence for the alternative and WSIP settings, and the differences in flow between the two. The differences in flow between the alternative and WSIP settings at this location are the net sum of the differences identified for flow reaching the location from Alameda Creek and from San Antonio Creek. The difference in flow from upstream in Alameda Creek was previously identified as insubstantial. Along with the conclusion that flow differences in San Antonio Creek would not be substantial, modeled differences below the confluence are also considered insubstantial.

2.7 Crystal Springs and San Andreas Reservoirs

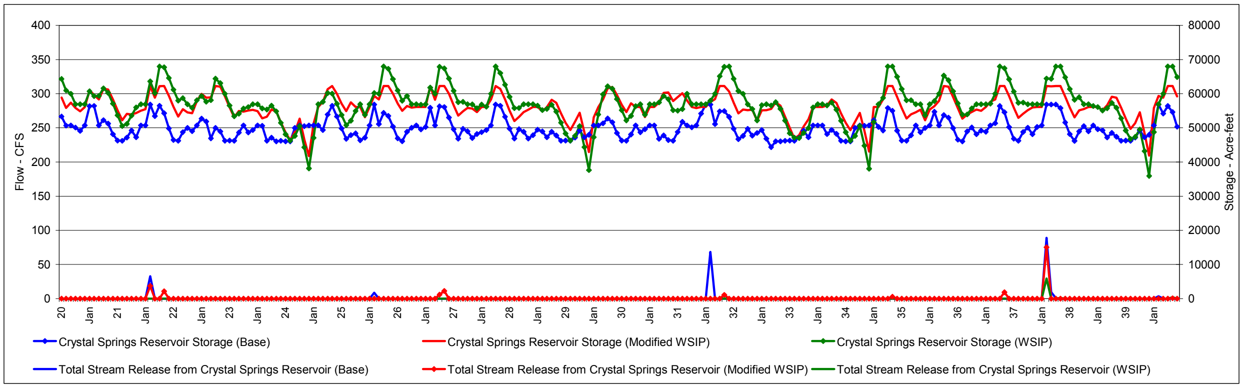
There are differences in Crystal Springs Reservoir operations between the WSIP setting and the alternative and base settings. Figure 2.7-1 illustrates a chronological trace of the simulation of Crystal Springs Reservoir storage and stream releases from Crystal Springs Dam. Shown in Figure 2.7-1 are the results for the WSIP, alternative, and base settings. Fundamental to the difference in storage operations between the WSIP and alternative settings and the base setting is the restoration of reservoir operation capacity, which does not occur in the base setting. The result is the operation of Crystal Springs Reservoir at a lower maximum storage in the base setting. The alternative setting differs from the WSIP setting in that the restored capacity of the Crystal Springs Reservoir is not fully used in the alternative setting. The Crystal Springs Reservoir restricted storage measure affects the maximum storage attained in the reservoir. Rather than having the full reservoir capacity of 22.15 billion gallons to regulate and store water, the reservoir is operationally constrained to a maximum of 20.28 billion gallons.

The operation of Crystal Springs Reservoir storage is generally consistent for the alternative and WSIP settings, except in the alternative setting the reservoir is not filled to the same level of storage. The annual drawdown of the reservoir occurs to about the same level. The alternative setting would provide less carryover storage at Crystal Springs Reservoir into periods of drought and would thereby cause additional draw from other resources to serve the same delivery. The magnitude of the draw of storage from Crystal Springs Reservoir is partially dependent on the discretionary assumptions of the model that proportions the use of storage among the Bay Area system reservoirs. In actual operations, some of these differences may not occur, as system operations and prevailing hydraulic and hydrologic conditions may result in a different apportionment of effect among the reservoirs. However, the operational strategy prefers the retention of storage in the Peninsula reservoirs, similar to the strategy used by the model. Figure 2.7-2 illustrates the average monthly storage in Crystal Springs Reservoir for the 82-year simulation, and the range in storage for each month for the alternative and WSIP settings.

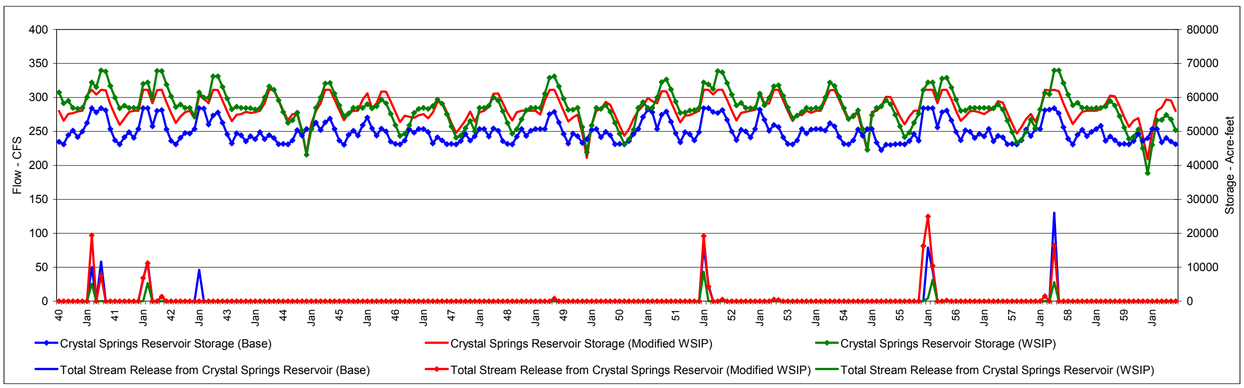
APPENDIX O2

Figure 2.7-1
Crystal Springs Reservoir Storage and Release

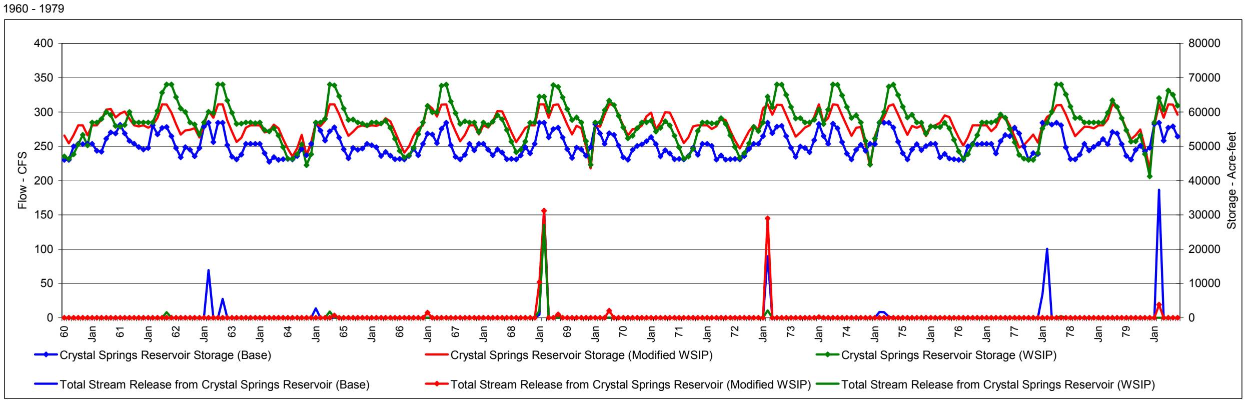
1920 - 1939



1940 - 1959



1960 - 1979



1980 - 2002

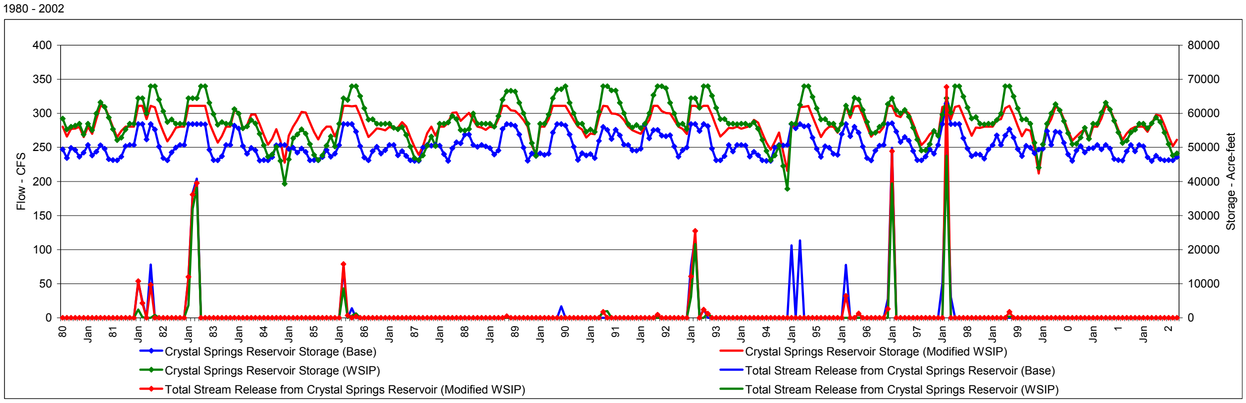


Figure 2.7-2

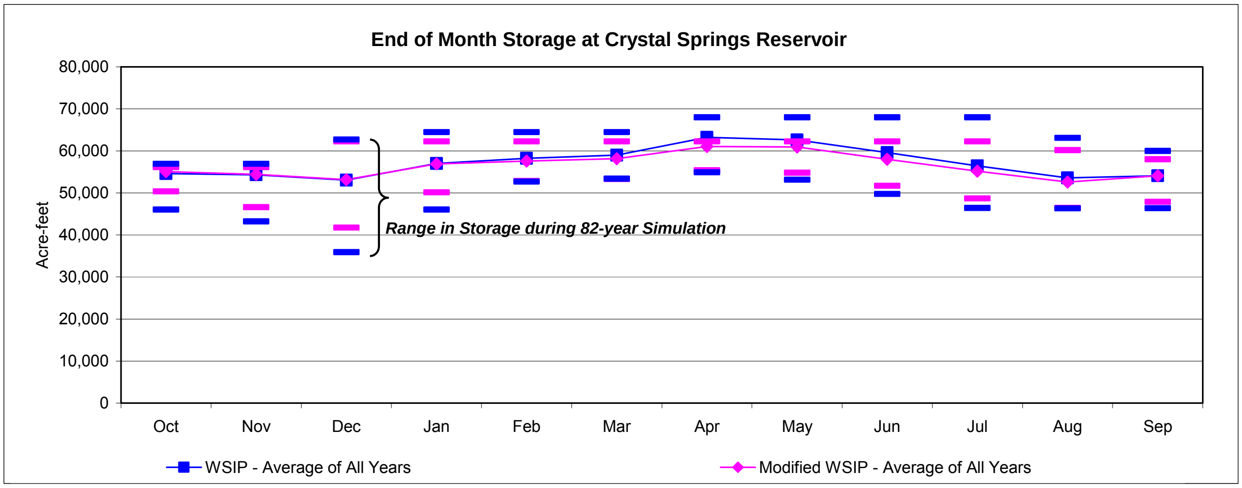

Figure 2.7-3 illustrates the average monthly storage in Crystal Springs Reservoir for the 82-year simulation, and the range in storage for each month for the alternative and base settings. The alternative setting would result in reservoir storage operating at a slightly higher average level during all months, and the range of operating storage would typically be smaller in the alternative setting, except during the system maintenance cycle.

Figure 2.7-3

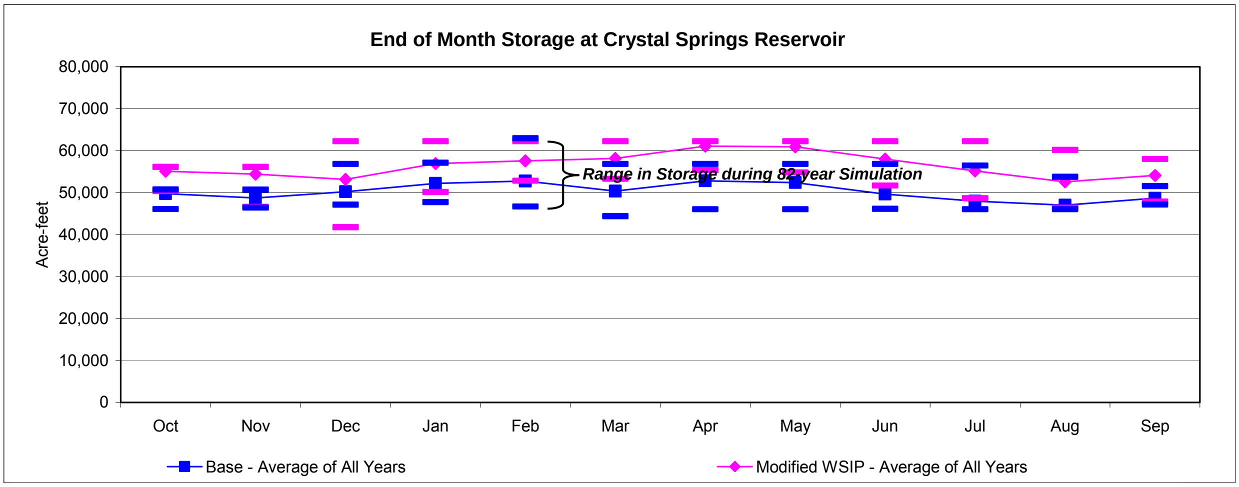

Table 2.7-1 illustrates the modeled alternative and WSIP stream releases from Crystal Springs Reservoir and the differences between the two settings. Modeling results indicate that an increase in the occasional release could occur. The potential difference is attributed to a narrower operating range of reservoir storage in the alternative setting. This narrower range in storage would lead to a greater potential for stream releases. In actual operations, it is anticipated that system operators would manage the reservoir system whereby stream releases would be minimal under any setting, and the effect would be essentially no difference between the alternative and WSIP settings. Similarly, Table 2.7-2 illustrates the stream releases for the alternative and base settings, and the difference in modeled flows between the two settings. A lesser drawdown in Crystal Springs Reservoir storage associated with the alternative setting would lead to a decreased potential to regulate reservoir inflow, which would lead to additional risk in needing to make stream releases. However, as described above, actual system operations attempt to minimize releases under any setting, and thus the difference in releases between the alternative and base setting is minimal, if any.

Reservoir storage at San Andreas Reservoir would follow a systematic filling and lowering each year; however, there would be slight differences in drawdown between the alternative and WSIP settings, primarily due to the coincidence of the effects of different systemwide maintenance and water demands within each setting. Figure 2.7-4 illustrates a chronological trace of the simulation of San Andreas Reservoir storage and stream releases from San Andreas Dam. Shown in Figure 2.7-4 are the results for the WSIP, alternative, and base settings. There are no projected stream releases from San Andreas Reservoir in any setting. Compared to the base setting, as Figure 2.7-4 illustrates, there would be a difference in storage operation every fifth year for the WSIP and alternative settings. These differences would be the result of Hetch Hetchy conveyance maintenance, which is assumed to occur systematically in the alternative and WSIP settings. The maintenance constrains the amount of Hetch Hetchy water supplied to serve water demands in the Bay Area. As previously discussed, during these winter periods the Bay Area reservoir system would accommodate the reduction in imported supply by serving the Bay Area water deliveries with the local watersheds' runoff and storage. At San Andreas Reservoir, serving this water demand would affect the reservoir when additional required water production at Harry Tracy WTP associated with WSIP or the alternative exceeded the ability to maintain San Andreas Reservoir storage with pumping from Crystal Springs Reservoir. In the modeling, the conveyance capacity from Crystal Springs Reservoir is assumed to be the same among all of the settings. The additional water demand of the WSIP and alternative require additional production from Harry Tracy WTP to be drawn from San Andreas Reservoir.

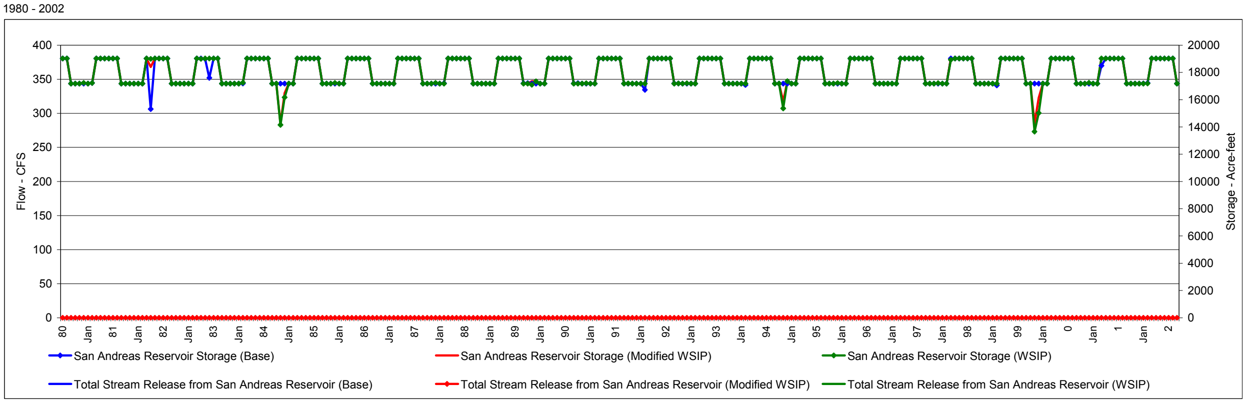

Figure 2.7-5 illustrates the average monthly storage in San Andreas Reservoir for the 82-year simulation, and the range in storage for each month for the alternative and base settings.

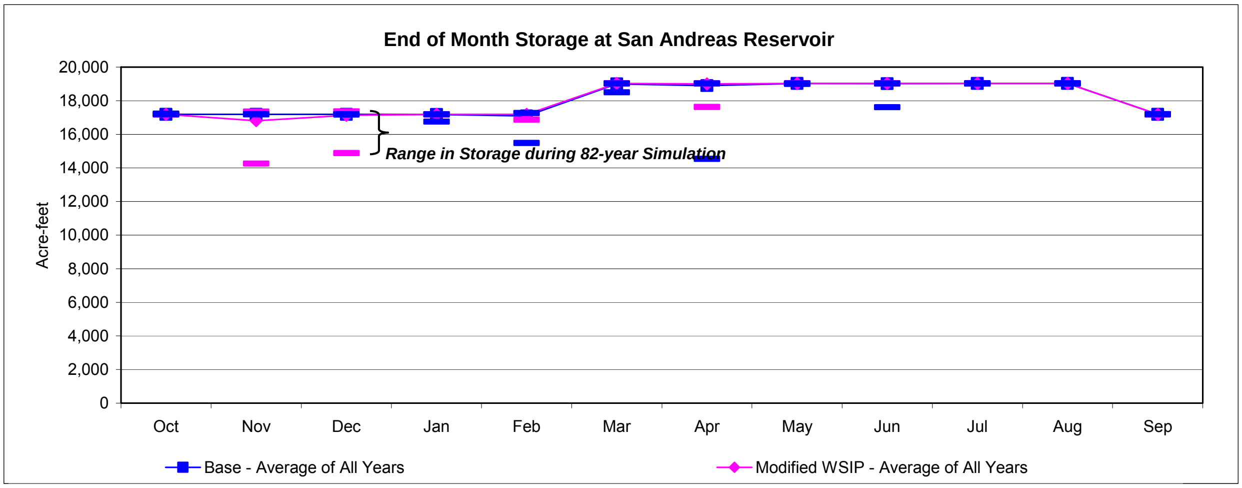
Figure 2.7-5



2.8 Pilarcitos Reservoir

Coastside County Water District's (Coastside CWD) water demand and its SFPUC purchase request are projected to increase within the WSIP planning horizon of year 2030. Within the context of the 2030 purchase request of 300 mgd, Coastside CWD's portion is estimated to amount to about 3 mgd. This projected purchase request is approximately 1 mgd greater that its current purchase request. Considering the current physical constraints on deliveries from the SFPUC to Coastside CWD and the ongoing planning activities in the watershed, the precise means of serving Coastside CWD's additional purchase request, and the resultant potential changes in the operation of SFPUC facilities and their affected environs, are uncertain.[2]

Assuming a range of potential means to serve the additional purchase request from Coastside CWD, the following are potential hydrologic effects on SFPUC facilities and their affected environs:

- Due to limited yield from Pilarcitos Reservoir, additional diversions would be required from Crystal Springs Reservoir.
- If deliveries to Coastside CWD from Pilarcitos Reservoir increase during the fall/winter/spring seasons, these deliveries could potentially reduce storage in Pilarcitos Reservoir, thereby potentially reducing diversions to the San Mateo Creek watershed. Although the increased delivery would increase releases to Pilarcitos Creek from Pilarcitos Dam for a period of time, the increase would subsequently lead to a reduction in spills past Stone Dam.
- Additional fall/spring/winter deliveries could also potentially impair the ability to provide carryover storage into the summer season from Pilarcitos Reservoir, and subsequently lead to an acceleration of the beginning of the season when releases to Pilarcitos Creek from Pilarcitos Reservoir consist only of the passage of reservoir inflow.
- An increase in summertime deliveries from Pilarcitos Creek could also accelerate the beginning of the season when releases to Pilarcitos Creek from Pilarcitos Reservoir consist only of the passage of reservoir inflow.

In the WSIP setting, Coastside CWD is assumed to increase its SFPUC demand from 1.8 mgd (average annual purchase request) to 3 mgd. It is also assumed that the month-to-month shape of Coastside CWD's future purchase request to the SFPUC system would follow the existing monthly shape. Currently,

---

2 See *Analysis of SFPUC PIlarcitos/Coastside County Water District Operations*, Memorandum by Daniel B. Steiner, March 8, 2007.

Coastside CWD can only receive a maximum of 2 mgd from the Pilarcitos Creek system due to the capacity of the connection to the Stone Tunnel, and it reaches its maximum delivery rate during the summer in the base setting. It is assumed that Coastside CWD would increase its delivery from Stone Dam following the shape of its increase in demand during the months when it currently does not reach the 2 mgd capacity (e.g., fall/winter/spring). By taking delivery of additional Pilarcitos Creek water in the fall/winter/spring, there are times when Pilarcitos Reservoir would not fill during the ensuing winter and thus the additional delivery would affect the carryover of reservoir storage into the summer. The effect is that the reservoir could empty to the spillway invert earlier in the summer than in the base setting. The effect would then cause the creek below Pilarcitos Reservoir to experience only reservoir inflow as compared to a controlled release (larger) out of the reservoir. A way to avoid or reduce this effect would be to provide extraction (pumping) of reservoir storage during the summer to maintain controlled releases to the creek in excess of reservoir inflow. The measure is modeled by allowing the Coastside CWD delivery to be met from Pilarcitos Reservoir storage even if the spillway crest has been reached, inferring pumping out water below the spillway invert.

The summer flow reduction in the WSIP setting (compared to the base setting) occurs in about 25 percent of the years, during one or more of the months of July through September. There are a few exceptions of years when the effect occurs in months prior to July. The effect typically manifests as one additional month of flow reduction in a year, amounting to about 150 to 190 acre-feet. The worst event was a reduction in two months of a year (1947), amounting to about 300 acre-feet.

The July through September flow reduction effect could be ameliorated by allowing water to be extracted from the reservoir below the spillway invert to meet the Coastside CWD delivery request during the summer. The model allows Pilarcitos Reservoir to operate at a lower minimum storage for the months of July through September. Figure 2.8-1 illustrates a chronological trace of the simulation of Pilarcitos Reservoir storage and stream releases from Pilarcitos Dam. Shown in Figure 2.8-1 are the results for the WSIP, alternative, and base settings. The alternative setting includes an allowance to draw up to 300 acre-feet from Pilarcitos Reservoir below the spillway invert to maintain July through September flows in Pilarcitos Creek.

The effect of the assumed Coastside CWD operation in combination with the effects of the overall SFPUC regional system operations would be occasional differences in the storage operation of Pilarcitos Reservoir. Overall, there would be a slightly lower average storage at Pilarcitos Reservoir. Figure 2.8-2 illustrates the average monthly storage in Pilarcitos Reservoir for the 82-year simulation, and the range in storage for each month for the WSIP and base settings.

Figure 2.8-1 illustrates the result of allowing the reservoir to go below the spillway invert during July through September in the alternative setting. The 300-acre-foot value is representative of the largest effect of the WSIP in a year (1947) for the July through September period. The hydrograph illustrates that the measure is not needed every year, and the full 300 acre-feet of the measure is rarely used. In effect, the measure assures controlled flow during the July through September period, even if the base did not have controlled flow. Several factors contribute to other changes in Pilarcitos Reservoir storage. At times, additional water is drawn from Pilarcitos Reservoir to the San Mateo Creek watershed in reaction to additional demands being served from the SFPUC system. Pilarcitos Reservoir is at times also drawn to meet the increase in demand from Coastside CWD during months (e.g., spring months) when available conveyance capacity from Stone Dam exists. Both of these additional draws from the reservoir would deplete storage below that experienced in the base setting. Pilarcitos storage would typically replenish at the expense of future reservoir spills, or within a year storage would end the same and the reservoir would still reach the minimum level at the spillway invert.

1960 - 1979
1980 - 2002

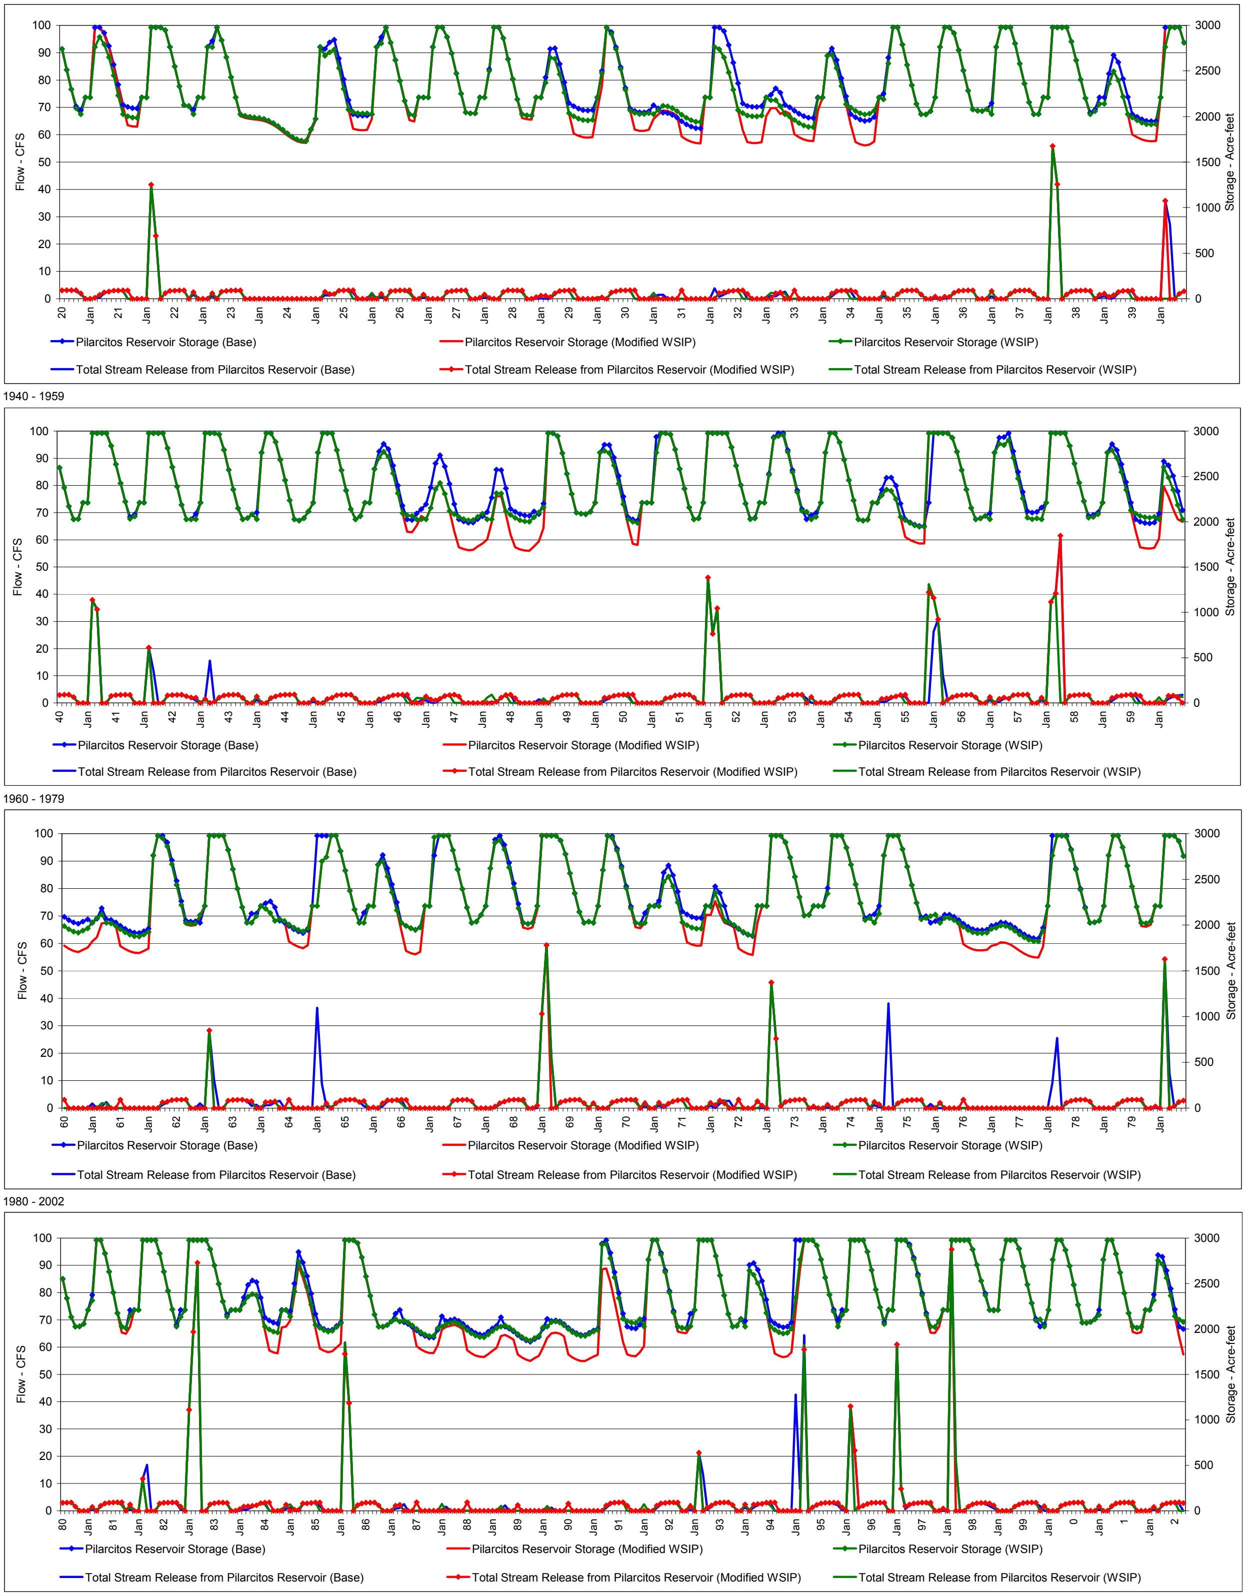

Figure 2.8-2

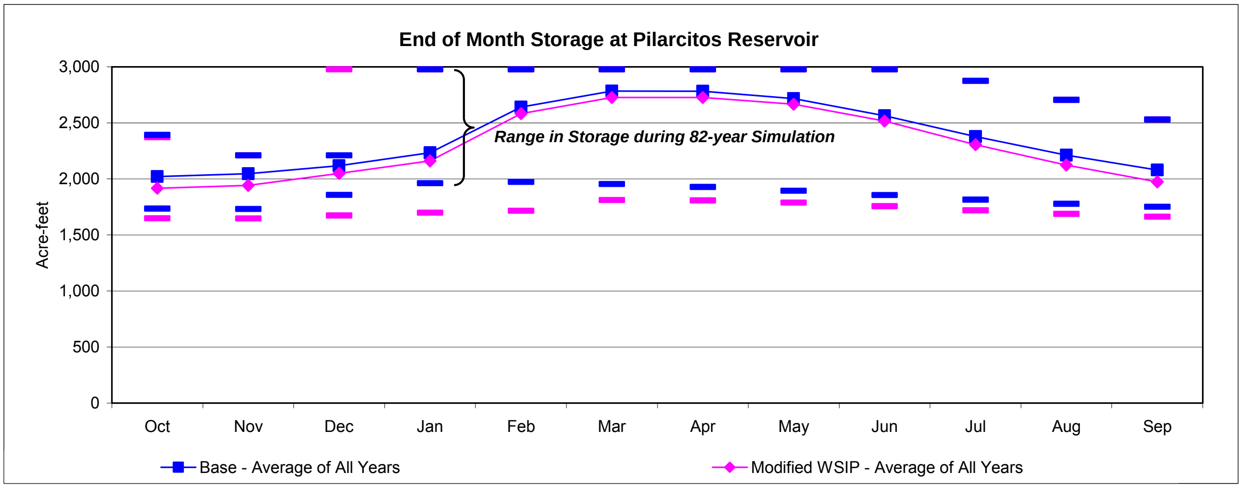

Stream releases from Pilarcitos Dam are also shown in Figure 2.8-1. Releases can occur for diversions at Stone Dam for Coastside CWD deliveries, conveyance to the San Mateo Creek watershed (e.g., Crystal Springs Reservoir), and reservoir spills. Pilarcitos Creek typically gains flow from unregulated tributary streams and runoff below Pilarcitos Dam. The differences in flow between the alternative and WSIP settings are shown chronologically in Table 2.8-1. The differences in flow between the alternative and base settings are shown chronologically in Table 2.8-2. The results shown in these two tables illustrate that the alternative's flow measure would ameliorate all summer (July through September) flow reductions associated with the WSIP, and at times would provide flow in excess of the flow occurring in the base setting.

Table 2.8-3 summarizes monthly average flow within year types for the comparison of the alternative and WSIP settings. Table 2.8-4 provides the same information for the alternative and base settings. When compared to the base setting, the alternative setting would result in positive changes in flows during the winter and spring, which are indicative of the additional draw of water from the reservoir to serve the increased demand of Coastside CWD during the period when conveyance capacity to Coastside CWD exists from Stone Dam. In this same comparison, the few reductions in flow during the early summer are indicative of years when additional releases earlier in a year would lead to the reservoir being depleted to minimum storage earlier in the year, thus reducing the amount of water released in a later month. During the summer, the increased releases are indicative of the alternative's flow measure. Reductions in flow during the winter and spring are indicative of the reservoir replenishing additionally depleted storage associated with the alternative setting.

The effect of the WSIP on Pilarcitos Creek flows below Stone Dam differs from the effect on flows below Pilarcitos Dam. Figure 2.8-3 illustrates the chronological trace of inflow to Stone Dam, which includes releases from Pilarcitos Dam to Pilarcitos Creek and unregulated flow to the stream below Pilarcitos Dam, and releases (spills) from Stone Dam to Pilarcitos Creek. Shown in the figure are the results for the alternative, WSIP, and base settings. The flow past Stone Dam in all the settings is typically minor (zero in modeling results, but may be measurable in terms of leakage and seepage past the dam), as inflow to the dam is diverted to Coastside CWD or to the San Mateo watershed. Releases past Stone Dam typically occur when unregulated flow below Pilarcitos Dam exceeds the delivery needs of Coastside CWD at a time when the storage level at Crystal Springs Reservoir rejects the water from the Pilarcitos watershed. During times when inflow to Stone Dam is reduced due to reduced spills from Pilarcitos Reservoir, there are still substantial spills from Stone Dam to Pilarcitos Creek from the unregulated flow below Pilarcitos Dam.

In comparison to the base setting, the changes in flow below Stone Dam in the alternative setting would typically occur during the rainy season between the months of January and March, in at least one month during about half of the years. Tables 2.8-5 and 2.8-6 summarize the results of the alternative, WSIP, and base settings in terms of average monthly flows by year type, and the average differences in flow among the settings.

APPENDIX O3

Memorandum

Subject: **HH/LSM Assumptions and Results – WSIP Variants 2018 WSIP**

From: **Daniel B. Steiner**

Date: **May 6, 2008**

1. Introduction

This memorandum summarizes assumptions for and describes the interpretation of HH/LSM results for the simulation of the WSIP variant referenced as the “2018 WSIP.” The PEIR analyzed three WSIP variants described as: WSIP Variant 1 - All Tuolumne; WSIP Variant 2 - Regional Desalination for Drought; and WSIP Variant 3 - 10% Rationing. The major difference between the variants and the proposed program (WSIP) was either in the proposed source(s) of water supply or in the drought-year rationing level of service (LOS). The 2018 WSIP variant supplements the previously described analyses. Tables 1-1 and 1-2 summarize the components, various modeling assumptions, and performance and hydrologic results for the 2018 WSIP variant in comparison to the modeled existing (2005) base setting (with Calaveras Reservoir constrained by DSOD restrictions) and the WSIP setting.

The hydrology that would result under this variant is primarily discussed in terms of a comparison to the WSIP and contrasted to the baseline condition of the PEIR, namely the simulated current (2005) operation of the SFPUC regional water system assuming that the Calaveras and Crystal Springs Reservoirs operation are constrained by DSOD restrictions. Only primary hydrologic parameters such as projected water deliveries, reservoir storage, and stream flows are compared, and only those parameters that have been identified as key hydrologic factors that lead to environmental impacts are illustrated.

Notes for Table 1-1 and Table 1-2

1. Baseline condition represents the existing conditions at the time of NOP publication in September 2005. This is the baseline used to assess WSIP program impacts and impact significance. This setting is indicative of DSOD restrictions on Calaveras and Crystal Springs Reservoirs.

2. N/A

3. These scenarios represent CEQA alternatives that vary from the WSIP on key components in a manner expected to avoid or reduce potentially significant effects of the proposed program.

4. The time horizon for the setting of the scenario. The baseline condition scenario is depicted for recent conditions, while the proposed WSIP, variants, and alternatives are depicted for the future at full buildout and implementation (i.e., conditions in the year 2030). The 2018 WSIP variant assesses conditions at the time that full current contract buildout occurs.

5. HH/LSM simulation study name.

6. The customer purchase request (demand) information is based on the demand and request studies prepared by the SFPUC in coordination with the wholesale customers. This demand on the regional water system includes both the SFPUC retail customers and wholesale customers. The current (2005) average annual demand is 265 mgd and the projected 2030 average annual demand is 300 mgd, assuming the SFPUC adopts the updated wholesale customer purchase requests as part of renewing the Master Sales Agreement with these customers (due in 2009).

7. Certain scenarios include development of additional water supply from a combination of recycled water projects, groundwater projects, and conservation, utilized every year and not subject to reduction during drought.

8. The average annual demand for supplies from the combination of SFPUC local watershed, Tuolumne River, and programs not included in the regional water conservation, recycling, and groundwater programs shown.

9. Modeled results for SFPUC deliveries, with supplies added for regional water conservation, recycling, and groundwater programs. Total deliveries and supply will be less than full customer purchase requests due to rationing in some years.

10. Shows only the features that affect hydrologic results of the system operation simulations. Additional projects are included in the WSIP, variants and alternatives.

11. Illustrates the frequency and severity of water supply action or the severity of systemwide rationing. Only years when variable water supply component is implemented or rationing occurs are shown. "DD" illustrates the shortage results for years included in the prospective drought period of the SFPUC design drought. These years contribute to establishing system operation protocols but are not included in the hydrologic assessment analyses.

12. Rationing policy cap: The SFPUC WSIP level of service goal is to maintain rationing on the regional system at no more than 20% during any one year of the drought. Some alternatives do not achieve this level of service goal. Performance is indicated for the Design Drought ("DD") sequence and for the "Historical" hydrologic sequence.

13. Water supply elements develop water in different amounts from year-to-year, and in some instances only develop water during dry years. This information is provided to illustrate a comparison between local watershed supplies, Tuolumne River supplies and other identifiable water supplies used to meet system purchase requests. Values are stated in units of average annual quantities during the simulated historical sequence.

14. Results from HH/LSM analysis of each scenario. Values represent the average annual production of each element of supply during the design drought period.

15. Simplified calculation of system deliveries during the SFPUC design drought. The value represents the application of system-wide shortages to the demand level being met with SFPUC local watershed, Tuolumne River, and other developed supplies and does not include supplies from regional water conservation, recycled water or groundwater projects. Average value may be slightly misstated (up to 3 mgd) due to metric of analysis that does not account for differences in residual storage between studies. "Nominal" Firm Yield represents the yield of each scenario after adjustment for minor residual storage differences.

16. Supplemental releases from Calaveras Reservoir for fisheries (1997 CDFG MOU) of up to 6,300 acre-feet per year and the Alameda Creek recapture facility project are tied to implementation of the Calaveras Dam Replacement project (SV-2). When the dam is replaced and capacity restored, the flow release and recapture will both occur. The release requirement is based on supplementing other occurring flows below Calaveras Reservoir, sometimes not requiring the full 6,300 acre-feet.

17. SFPUC actions are assumed to not change TID/MID diversions so as to isolate and possibly overstate the WSIP's effects on the Tuolumne River below La Grange Dam. The Districts' diversions are assumed to be constant among the scenarios to provide comparable results of the WSIP-alone effects. The exception is for the Modified WSIP Alternative, in which the TID/MID diversion is reduced by the amount of SFPUC transfer.

18. Participation in the San Joaquin River Agreement is assumed. Although the agreement expires after 2010, it is assumed that a subsequent similar agreement or requirement of the Districts will occur. The HH/LSM does not explicitly model the Districts' participation in the agreement; however, their participation if modeled would result in only minor differences in results and would not change impact conclusions.

19. From HH/LSM results for modeling the SFPUC design drought period.

20. From HH/LSM results for modeling the system operations for the historical hydrologic period 1921-2002. Values indicate average annual quantities during simulated historical period.

APPENDIX O3

2. WSIP Variant – 2018 WSIP

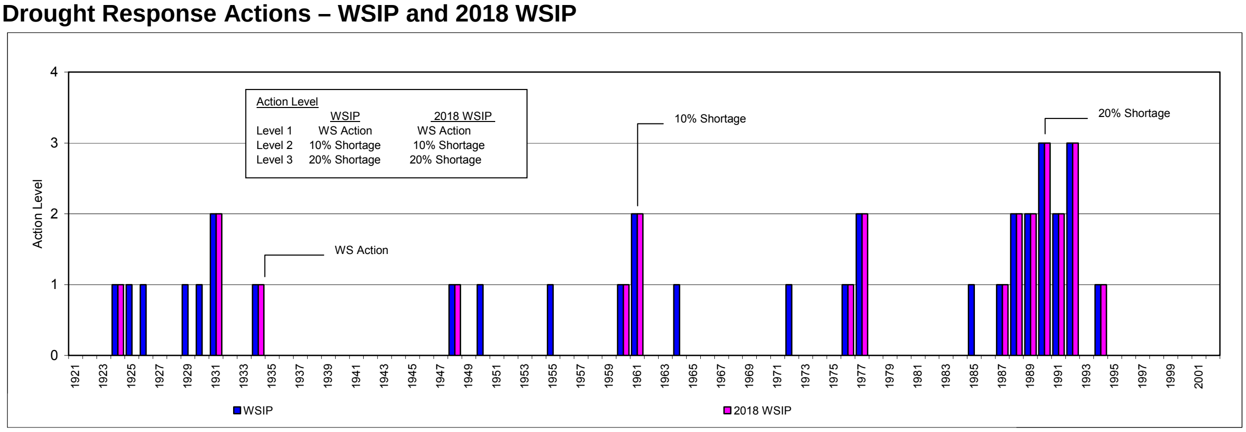
The 2018 WSIP variant would in effect be a combination of the proposed WSIP and the water purchase request of the CEQA No Purchase Request Increase Alternative applicable for the period through the year 2018. This variant would limit the SFPUC wholesale customers' interim future purchases to the terms of the existing Master Water Sales Agreement through 2018. Under that agreement, the wholesale customers may purchase up to 184 mgd on an average annual basis, subject to reductions in the event of a drought, water shortage, earthquake, other natural disaster, or rehabilitation and maintenance of the system. Under the variant, the customer purchase requests through 2018 would not exceed 184 mgd for the wholesale customers. It is assumed that the total customer purchase requests to be served by the regional system through 2018 would be 275 mgd, consisting of 184 mgd for the wholesale customers and 91 mgd for the retail customers. The increased water demand would be offset with 10 mgd from recycled water, groundwater, and conservation projects in San Francisco. Although the net demand through 2018 on the regional water system would be the same as the current demand (265 mgd), the improvement in delivery reliability requires development of additional system yield. The additional deliveries would be served through additional Tuolumne River diversions and increased use of local watershed supplies from restoration of Calaveras Reservoir and Crystal Springs Reservoir. Supplemental supplies would include implementation of the Westside Basin Groundwater Program and a water transfer with TID/MID.

In the context of the WSIP planning horizon for the year 2030, this analysis provides insight into the hydrologic effects of the program at an interim point in time (2018), or it provides a depiction of the WSIP if a delivery limitation is continued through 2030. Should the deliveries of the regional system be allowed to increase after 2018, the analysis described for the WSIP depicts the hydrologic effects associated with increased deliveries. The following description focuses on the time at which the variant's net demand of 265 mgd would occur.

2.1 Water Deliveries and Drought Response Actions

Compared to the WSIP setting for 2030, the regional system's resources are required to serve a net 265 mgd demand (275 mgd purchase request less 10 mgd of recycled water, groundwater, and conservation projects) instead of a net 290 mgd demand. As part of the formulation of this variant, the water transfer from TID/MID was sized to provide the same frequency and severity of water shortages (percentage-wise) for the variant as that occurring in the WSIP setting during the design drought, although systemwide water deliveries would be a net 265 mgd in the variant setting as compared to the WSIP setting delivery of a net 290 mgd. This objective required the water transfer to be sized at 2,300 acre-feet per year. With a water supply formulated about comparable to that provided for the WSIP setting (only proportionately smaller for a lesser demand), the implementation of rationing and the severity of rationing from the SFPUC system during drought periods would be the same. Table 1-1 compares the drought response actions for the proposed program and the variant. Figure 2.1-1 illustrates the occurrence of drought response actions for the simulated 82-year historical period (1921-2002).

Figure 2.1-1
Drought Response Actions – WSIP and 2018 WSIP

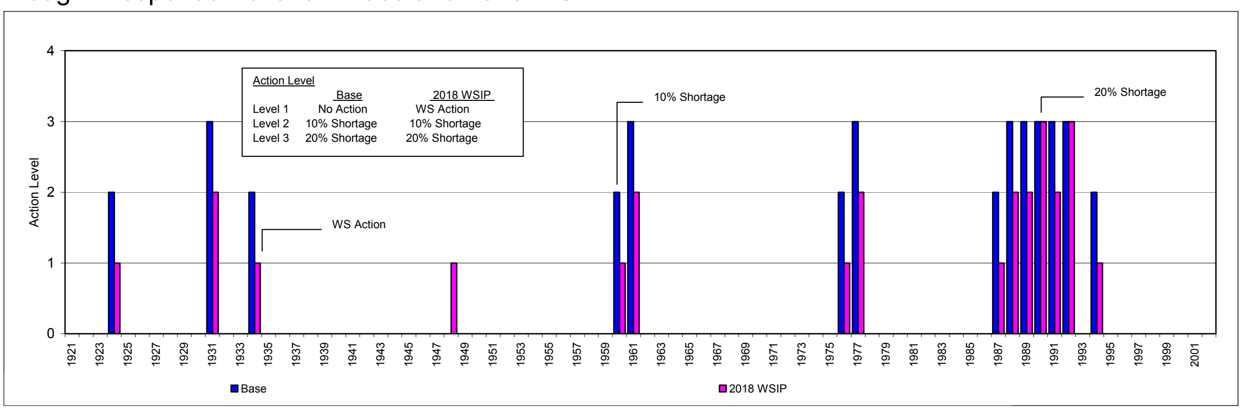


APPENDIX O3

In Figure 2.1-1, years with bars showing a “1” or greater level of action indicate periods when a supplemental water supply action is initiated. In both settings, the water supply action is the use of the Westside Groundwater Basin Program to supplement SFPUC water deliveries. Also occurring in both settings is the water transfer supplemental supply from TID/MID every year. Action levels greater than “1” indicate the imposition of delivery shortages (rationing) to SFPUC customers. SFPUC customers would experience the same frequency and severity of shortages (percentage-wise). The triggering of the Westside Basin Groundwater Program supplemental supply would occur more frequently in the WSIP setting, typically as a precautionary response to potential prolonged drought or to retain local area storage. With the lesser demand of the variant, a less frequent precautionary response would be needed.

The same form of information is shown in Figure 2.1-2 for the comparison between the variant and the base (existing) settings. There is not a level 1 action in the base setting. Without supplemental resources, the existing system only has delivery shortage measures available to cope with drought. In the base setting, the shortage measure is imposed during level 2 (10 percent) and level 3 (20 percent). These percentages of shortage are applied to both the variant and the base settings for these action levels, and they are applied to the same level of net water demand (265 mgd). During this simulation period, rationing would not need to exceed 20 percent in either setting; however, in the variant setting the occurrence of additional water supplies lessens the frequency and severity of water delivery shortages.

Figure 2.1-2
Drought Response Actions – Base and 2018 WSIP



Not illustrated in Figure 2.1-2 but shown in Table 1-1 are the delivery shortages anticipated during the entire SFPUC design drought. During the design drought, the base setting does not have a viable operation without exceeding a 20 percent shortage level. The base setting exceeds the 20 percent shortage level (requires 25 percent rationing) during the last 18 months of the design drought. The variant would viably provide deliveries without exceeding a 20 percent shortage level.

The difference in water deliveries between the proposed program and the variant is shown chronologically for the 82-year simulation in Table 2.1-1. There would be less water delivered to the region by the SFPUC in all years, a result of serving a lesser purchase request (275 mgd instead of 300 mgd, and a lesser net demand of 265 mgd instead of 290 mgd).

Comparing the variant setting to the base setting, Table 2.1-2 illustrates the difference in water deliveries between the two settings. The increases in deliveries under the variant setting occur due to an improvement in water delivery reliability, which reduces the severity of water shortages. The shifting in the pattern of deliveries (most evident during years when there is no increase in total annual delivery) is indicative of the anticipated seasonal effect of recycled water, groundwater, and conservation projects within the pattern of the projected future, albeit limited, purchase request. The 82-year average increase in deliveries amounts to approximately 3.5 mgd.

APPENDIX O3

Table 2.1-1

Difference in Total System-wide Delivery (MG) 2018 WSIP minus WSIP

2.2 Diversions from the Tuolumne River

The metric for illustrating the SFPUC diversions from the Tuolumne River Basin (Tuolumne) is the flow through the San Joaquin Pipeline (SJPL). Inherent in the variant is a net water demand that is essentially equal to that under the base setting, which is less than the demand served by the proposed program. Table 2.2-1 illustrates the difference in diversions to the SJPL between the proposed program and the variant settings. In both settings, the conveyance capacity of the SJPL is increased compared to the base setting. During the summer, the SJPL would essentially operate at the same maximum rate in both the variant and WSIP settings to minimize drawdown of Bay Area reservoir storage. A few exceptions occur during the summer of drought periods when the variant would serve a lesser demand than the WSIP. Overall, compared to the WSIP setting, the variant setting would divert less water from the Tuolumne.

Table 2.2-2 illustrates the difference in diversions to the SJPL between the variant and base settings. Evident in the operation is the increase in summer diversions associated with an increase in the conveyance capacity of the SJPL. As described above, with the increase in SJPL conveyance capacity, summer diversions would increase to retain storage in the Bay Area reservoirs. With the demand of the variant being approximately the same as the base setting, the increase in summer diversions to the SJPL would result in reduced diversions during the late summer and fall. The differences in December diversions are largely the result of maintenance in the variant setting (lessening available conveyance capacity) that would not occur in the base setting. The increased diversions during the winter and spring result from the need to replenish Bay Area reservoir storage after the maintenance, and then the operation of topping off Bay Area reservoir storage prior to summer. There would be an overall increase in average annual diversions to the SJPL in the variant setting associated with the improvement in water delivery reliability. The 82-year average annual increase in diversions from the Tuolumne amounts to approximately 1,900 acre-feet per year (1.7 mgd).

Table 2.2-3 illustrates the average monthly diversions through the SJPL by year type for the 82-year simulation for the proposed program and the variant settings and the difference between the two settings. Table 2.3-4 shows the same information for the variant and base settings.

APPENDIX O3

2.3 Hetch Hetchy Reservoir and Releases

Compared to the WSIP setting, the variant setting would draw less water from the Tuolumne due to the lesser demand. This circumstance would lead to less draw from Hetch Hetchy Reservoir in the variant setting in most years. Figure 2.3-1 illustrates a chronological trace of the simulation of Hetch Hetchy Reservoir storage and stream releases. Shown in Figure 2.3-1 are the results for the WSIP, variant (2018 WSIP), and base settings. Supplementing the Figure 2.3-1 representation of Hetch Hetchy Reservoir storage are Table 2.3-1, Hetch Hetchy Reservoir Storage (2018 WSIP); Table 2.3-2, Hetch Hetchy Reservoir Storage (WSIP); and Table 2.3-3, Difference in Hetch Hetchy Reservoir Storage (2018 WSIP minus WSIP). Table 2.3-4 is provided to illustrate the difference in Hetch Hetchy Reservoir storage between the base and variant settings.

Table 2.3-3 shows that, by the end of summer, storage in Hetch Hetchy Reservoir associated with the variant setting would be greater than the storage in the WSIP setting in about 20 percent of the years, ranging from a minor increase to over 31,000 acre-feet in a year. The relatively minor increases in storage are attributable to years when summer diversions would be the same in both settings (SJPL operating at maximum capacity) but less water would be diverted in the fall due to the lesser water demand. The larger increases in storage are associated with drought periods, during which the differences in underlying demand and water delivery shortages between the WSIP and variant settings are greater.

Through the fall and winter, storage in Hetch Hetchy Reservoir would be the same or higher under the variant setting. Hetch Hetchy Reservoir would fill by the end of May during approximately 82 percent of the years, which would prevent any difference in storage from affecting the next summer's reservoir storage. Figure 2.3-2 illustrates the difference in reservoir storage, averaged by year type, for the variant and WSIP settings. Also shown is the average difference in storage for the two settings during the 82-year simulation.

Table 2.3-4 illustrates the difference in Hetch Hetchy Reservoir storage between the variant and base settings. Immediately after filling Hetch Hetchy Reservoir (May or June, and then continuing through July), there would only be occasional differences in storage at the reservoir, typically a decrease of less than 12,000 acre-feet. This is indicative of the same amount of water being passed through the reservoir regardless of the size of the conveyance capacity of the SJPL. Water not diverted to the SJPL would return to the Tuolumne River and flow to Don Pedro Reservoir. In the late summer and early fall, there would consistently be a slight difference (lower) in storage levels between the two settings, as additional diversions to the SJPL would retain Bay Area reservoir storage. Some of this additional Hetch Hetchy Reservoir storage depletion would be ameliorated later in the fall and into winter as SJPL diversions are reduced due to less Bay Area reservoir replenishment needs and conveyance system maintenance. Storage becomes greater in November and December of the variant setting due to the assumed systemwide maintenance that would occur in the variant setting but not in the base setting. After December, the storage gain occurring in the variant setting would again be affected as replenishment of Bay Area reservoir storage resumes. In non-wet years, there is a difference in storage between the variant and base settings; the variant setting sometimes results in a lower storage in the reservoir by the end of April. Figure 2.3-3 illustrates the difference in reservoir storage, averaged by year type, between the variant and base settings. Also shown is the average difference in storage for the two settings during the 82-year simulation. Figure 2.3-4 illustrates the average monthly storage in Hetch Hetchy Reservoir for the 82-year simulation, and the range in storage for each month for the variant and base settings.

The difference in storage in Hetch Hetchy Reservoir attributed to the diversion effects of the variant would manifest in differences in releases from O'Shaughnessy Dam to the stream. A different amount of available reservoir space in the winter and spring due to the variant would lead to a different ability to regulate inflow, thus potentially changing the amount of water released to the stream that is in excess of minimum release requirements. Figure 2.3-1 illustrates the stream release from O'Shaughnessy Dam for the WSIP, variant, and base settings. Table 2.3-5 illustrates the difference in stream releases between the variant and WSIP settings. Compared to the WSIP setting, the variant exhibits an incrementally greater stream release, predominately during May or June, which is reflective of the months when releases to the stream are made in excess of minimum release requirements in anticipation of filling the reservoir. The exceptions to this circumstance, during which incrementally larger reductions in releases to the stream occur, are considered anomalous within the modeling and simply the result of shifting releases from one month to the next. The increase in releases is the result of a less-depleted reservoir, which is the result of lesser SFPUC demands between the settings.

Table 2.3-6 illustrates the difference in stream releases between the variant and base settings. In this comparison, releases could be either greater or less than depicted for the base setting, and these differences would occur predominately during May or June. Generally, Hetch Hetchy Reservoir storage would be slightly lower during non-wet years, leading to a reduction in stream releases during non-wetter years if a release occurs. During wetter years, the releases are projected to increase. The differences, either increases or decreases, are a result of the coincidence of several operational parameters affecting the release of water from the reservoir, including systemwide water demands, conveyance capacity and maintenance assumptions, and the watershed's hydrology.

Table 2.3-5 illustrates the difference in stream releases between the variant and WSIP settings, expressed in terms of a monthly volume (acre-feet) of flow. Table 2.3-7 illustrates the same information and the average monthly stream release for the variant and WSIP setting, expressed in average monthly flow (cfs). Table 2.3-5 shows an increase in monthly flow below O'Shaughnessy Dam of up to approximately 32,000 acre-feet. Considering the manner in which releases are determined and made to the stream, it is not always meaningful to quantify the effect of these changes in terms of average monthly

flow (cfs).[1] When comparing the variant to the WSIP setting, a change in the volume of release from O'Shaughnessy Dam to the stream would likely result in the release being delayed or initiated earlier by a matter of days. Typical springtime releases, when initiated, amount to a release of up to 3,000 cfs (approximately 6,000 acre-feet over the span of a day). Using the assumption that a change in release volume equates to a delay or an earlier initiation of releasing 6,000 acre-feet per day means that the difference in stream release between the variant and WSIP would be up to an added five days of release. Normally, this change in release would not affect the peak stream release rate during a year. Table 2.3-8 illustrates the average monthly stream release for the variant and base settings, and the differences, expressed in average monthly flow (cfs). Table 2.3-6 illustrates that the difference in monthly flow below O'Shaughnessy Dam between the variant and base settings could range from an increase of approximately 30,000 acre-feet to a decrease of approximately 36,000 acre-feet. Using the same metric as described above to estimate the delay or addition in the number days of release to the stream, the variant could lead to an effect ranging from an increase of five days of release to a decrease of up to 6 days compared to the base setting.

2.4 Lake Lloyd and Lake Eleanor

Compared to the operation of the WSIP, the operation of Lake Lloyd and Lake Eleanor are simulated to be only slightly different for the variant. Figure 2.4-1 illustrates a chronological trace of the simulation of Lake Lloyd storage and stream releases. Shown in Figure 2.4-1 are the results for the WSIP, variant, and base settings. The operation resulting from the variant is essentially the same as the WSIP setting, including during drought. Although the level of delivery between the variant and base settings is essentially the same (net 265 mgd demand) during the 1987-1992 drought, water delivery reliability has been improved in the variant setting; as a result, the drawdown of Lake Lloyd during this period looks closer to that in the WSIP setting. Although there is less water delivered during this period in the variant setting compared to the WSIP setting, more water is delivered in the variant setting than in the base setting. The additional draw of water reduced the amount of water released from Hetch Hetchy Reservoir to Don Pedro Reservoir in the variant setting, which, in order to satisfy TID/MID entitlements to inflow, was met with additional releases from Lake Lloyd, similar to the WSIP setting. The additional release from Lake Lloyd associated with the variant appears to be approximately the same as in the WSIP setting in this instance, which is partially a factor of modeling discretion in that the HH/LSM makes release decisions in the form of block amounts of releases. Additional refinement of modeling assumptions would likely produce a result that places Lake Lloyd storage during this drought period more between the base setting and WSIP setting results. Otherwise, the results for Lake Lloyd storage are essentially the same between the WSIP and variant settings.

Figure 2.4-2 illustrates the almost identical operation of Lake Eleanor for the variant and WSIP settings. Also shown in Figure 2.4-2 is the operation for the base setting. Any difference in the Lake Eleanor operation would be caused by a small change in operation at Lake Lloyd that would affect the operation of the Cherry-Eleanor Tunnel between the two watersheds. Any difference that occurs in the simulations is more likely the result of modeling discretion as opposed to any substantive difference in operation.

Supplementing the Figure 2.4-1 representation of Lake Lloyd stream releases is Table 2.4-1, which illustrates releases for the variant and WSIP settings, and the difference in releases between the two settings. Table 2.4-2 provides the same form of information for the variant and base settings. With essentially no change in reservoir operations, stream releases will not be different.

2.5 Don Pedro Reservoir and La Grange Releases

A change in Don Pedro Reservoir operation is caused by changes in inflow to the reservoir. The changes in inflow to the reservoir are the result of net changes within the operation of the upstream SFPUC facilities described previously, and other changes in SFPUC operations associated with diversions to the Holm, Kirkwood, and Moccasin Powerhouses. Figure 2.5-1 illustrates a chronological trace of the simulation of Don Pedro Reservoir storage and Tuolumne River stream releases from La Grange Dam. Shown in Figure 2.5-1 are the results for the WSIP, variant, and base settings. Supplementing the Figure 2.5-1 representation of Don Pedro Reservoir storage are Table 2.5-1, Don Pedro Reservoir Storage (2018 WSIP); Table 2.5-2, Don Pedro Reservoir Storage (WSIP); and Table 2.5-3, Difference in Don Pedro Reservoir Storage (2018 WSIP minus WSIP). Table 2.5-4 is provided to illustrate the difference in Don Pedro Reservoir storage between the base and variant settings.

Table 2.5-3 shows that, throughout many years, the storage in Don Pedro Reservoir associated with the variant setting would differ from the storage in the WSIP setting, and this difference would always be more storage. Table 2.5-4 illustrates that the variant setting results for Don Pedro Reservoir storage are close to the storage results depicted for the base setting, although typically lower than the base setting. Compared to the WSIP setting, the differences in storage are indicative of the increases to the inflow of Don Pedro Reservoir that are due to lesser demands and SJPL diversions in the variant setting. The increases in inflow typically occur during the winter through early summer period. Comparing to the base setting, the variant would result in typically less inflow to Don Pedro Reservoir during non-wet years and particularly during drought periods when more water is diverted to the SJPL in the variant setting. Less inflow leads to less reservoir storage.

Figure 2.5-1 and Table 2.5-4 illustrate that during drought sequences, a reduction to inflow to Don Pedro Reservoir can accumulate from year to year. Compared to the base setting, the variant would result in lower Don Pedro Reservoir storage during drought periods. Figure 2.5-2 illustrates the difference in reservoir storage averaged by year type for the variant and WSIP settings. Also shown is the average difference in storage for the two settings during the 82-year simulation. Figure 2.5-3 shows the same information for the variant and the base settings.

Figure 2.5-2

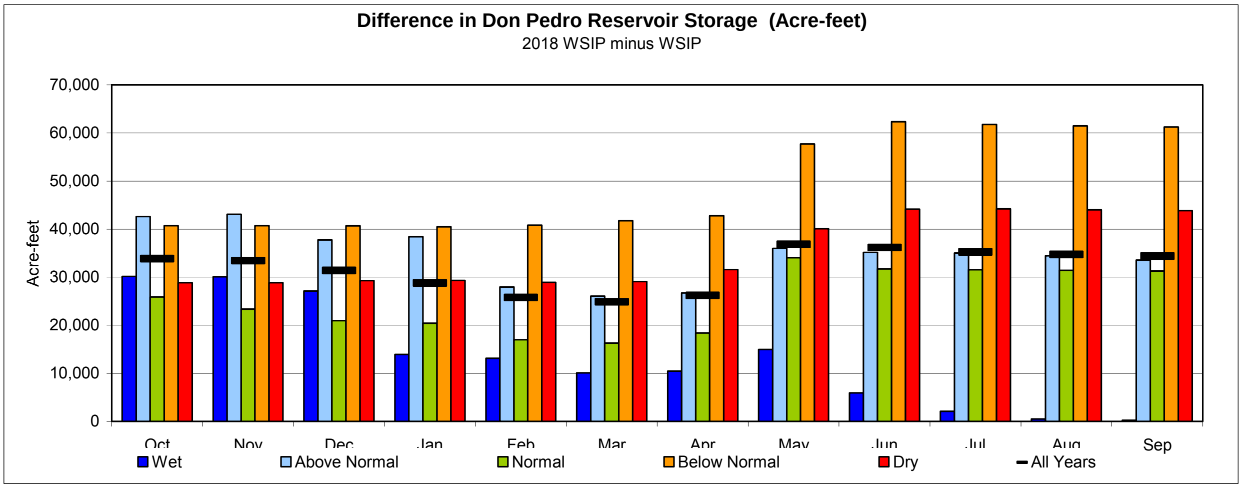

Figure 2.5-3

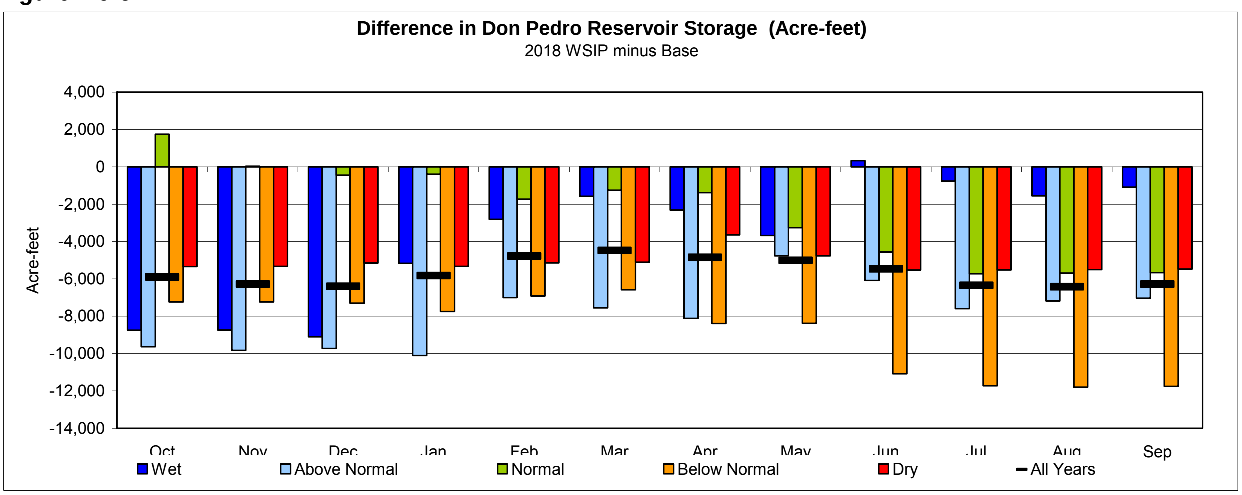

Figure 2.5-4 illustrates the average monthly storage in Don Pedro Reservoir for the 82-year simulation, and the range in storage for each month for the variant and base settings.

The difference in storage in Don Pedro Reservoir attributed to the upstream effects of the variant would manifest in differences in releases from La Grange Dam to the stream. A different amount of available reservoir space in the winter and spring due to the variant would lead to a different ability to regulate inflow, thus potentially changing the amount of water released to the stream that is in excess of minimum release requirements. During periods when inflow differs and Don Pedro Reservoir is at maximum storage capacity within the flood control storage limitation, a change in inflow directly manifests as a change in releases from La Grange Dam (a change of either more or less flow). Figure 2.5-1 illustrates the stream releases from La Grange Dam for the WSIP, variant, and base settings.

Figure 2.5-4

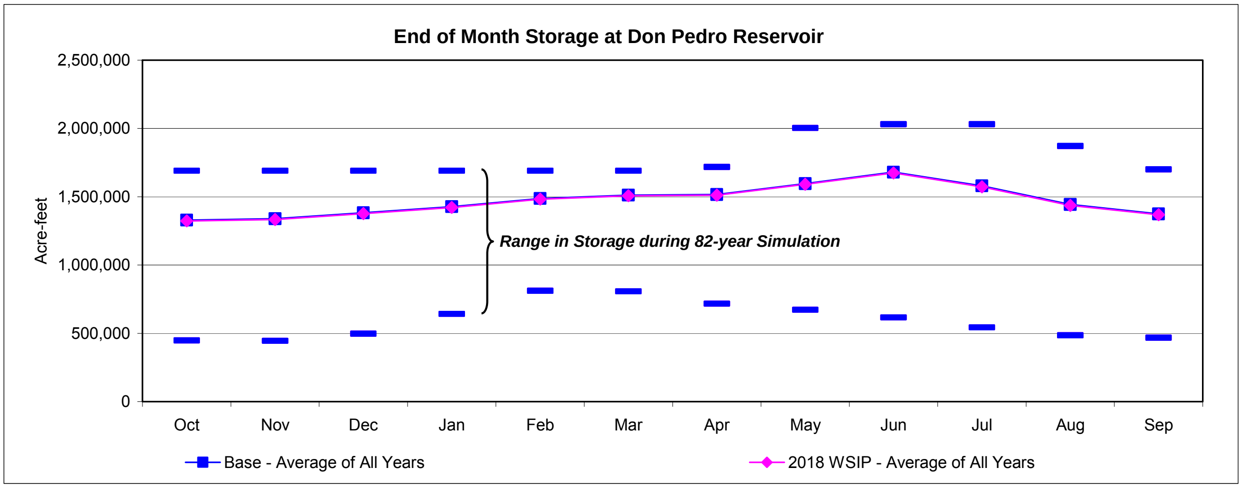

Table 2.5-5 illustrates the difference in stream releases between the variant and WSIP settings. Compared to the WSIP setting, the variant exhibits an incrementally larger stream release, predominately during some months of the early winter through June period, which is reflective of the months when releases to the stream are made in excess of minimum release requirements due to flood control or in anticipation of filling the reservoir. Table 2.5-6 shows the same information for the variant and WSIP settings, arranged by ranking the years in descending order of the San Joaquin River Index (an index of the wetness of the Tuolumne and San Joaquin River Basins). The table illustrates the finding that differences in releases to the Tuolumne River from La Grange Dam occur only when there are releases in excess of minimum FERC flow requirements. This circumstance typically occurs only in above-normal and wet years, and predominately during early winter through June. During other year types and during the summer and fall, releases would be maintained at minimum FERC flow requirements regardless of the setting. Compared to the WSIP setting, the large reduction in flow following an extended drought period is reduced with the variant, since the amount of water delivered by the SFPUC during these periods is less than that delivered in the WSIP setting, but is still more than delivered in the base setting.

As described above concerning Don Pedro inflow and storage, compared to the base setting the variant setting would lead to an additional draw of storage due to SFPUC diversions that are greater than in the base setting in drought periods. Although the reduction in storage would not greatly accumulate, greater replenishment of Don Pedro Reservoir storage would be needed in about 25 percent of the years in the 82-year simulation. There are occasions when an increase in releases would occur. This circumstance would result from the shift in timing of SJPL diversions due to the increased conveyance capacity. The effect would be an occasional additional release of water from Hetch Hetchy Reservoir in the winter that then manifests as an additional release from Don Pedro Reservoir. Table 2.5-7 illustrates the difference in stream releases between the variant and base settings, depicting the predominance of mostly slight reductions in flow. Table 2.5-8 illustrates the same information ranked in descending order of the San Joaquin River Index.

Table 2.5-5 and Table 2.5-7 illustrate the difference in stream releases among the variant, WSIP, and base settings, expressed in terms of a monthly volume (acre-feet) of flow. Table 2.5-9 presents the same information and the average monthly stream releases for the variant and WSIP settings, expressed in average monthly flow (cfs), and Table 2.5-10 shows the same information for the variant and base settings. For the comparison of the variant to the WSIP setting, the difference in monthly flow below La Grange Dam could range from an increase of approximately 179,000 acre-feet to a decrease of approximately 7,000 acre-feet. Considering the manner in which releases are determined and made to the stream, it is not always meaningful to quantify the effect of these changes in terms of average monthly flow (cfs). Similar to the operation of releases below O'Shaughnessy Dam, a change in the volume of release from La Grange Dam to the stream would likely delay or accelerate the initiation of the release by a matter of days. Using the assumption that a change in release volume equates to a delay or acceleration of releasing 6,000 acre-feet per day means that the difference in stream release from La Grange Dam between the variant and WSIP would be an additional day of delay in releases

APPENDIX O3

or up to almost an added month of release. Normally, a change in release would not affect the peak stream release rate during a year. However, infrequently (a rare event following a prolonged drought), the variant’s effect on stream releases could manifest as an elimination of all flow during a year or as the only provision of flow that occurs in excess of minimum FERC flow requirements. Compared to the base setting, the variant’s effect on stream flow ranges from a reduction in releases (a potential delay in release of 11 days) to an increase in releases (a potential additional 5 days of release).

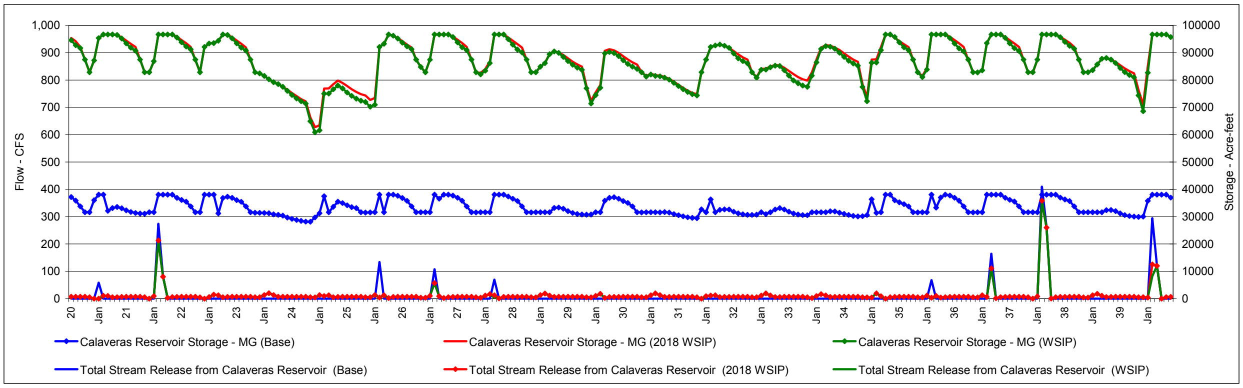
2.6 Calaveras and San Antonio Reservoirs, Alameda Creek, and Downstream

Compared to the WSIP setting, the operation of Calaveras Reservoir in the variant setting is almost identical. Figure 2.6-1 illustrates a chronological trace of the simulation of Calaveras Reservoir storage and stream releases from Calaveras Dam. Shown in Figure 2.6-1 are the results for the WSIP, variant, and base settings. In recognition of the different levels of systemwide deliveries served in each setting, the near identical operation of Calaveras Reservoir resulting from the two settings is an indication that Calaveras Reservoir operations are mostly influenced by the principles that manage local watershed production. The differences in reservoir operation during droughts are the result of modeling assumptions that balance reservoir storage among SFPUC reservoirs and the selection of the monthly SJPL conveyance rate. It is anticipated that the difference in Calaveras Reservoir operation during actual operations would be minimal, if any difference occurred at all.

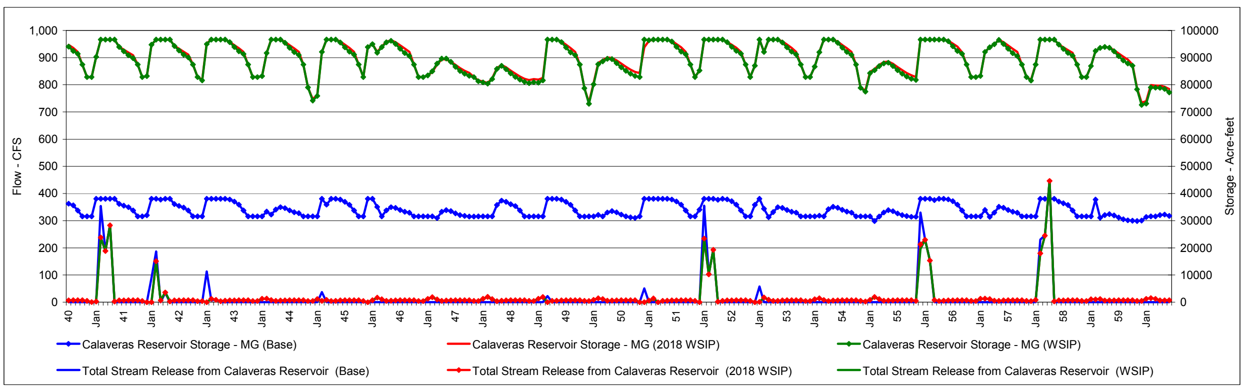
APPENDIX O3

Figure 2.6-1
Calaveras Reservoir Storage and Stream Release

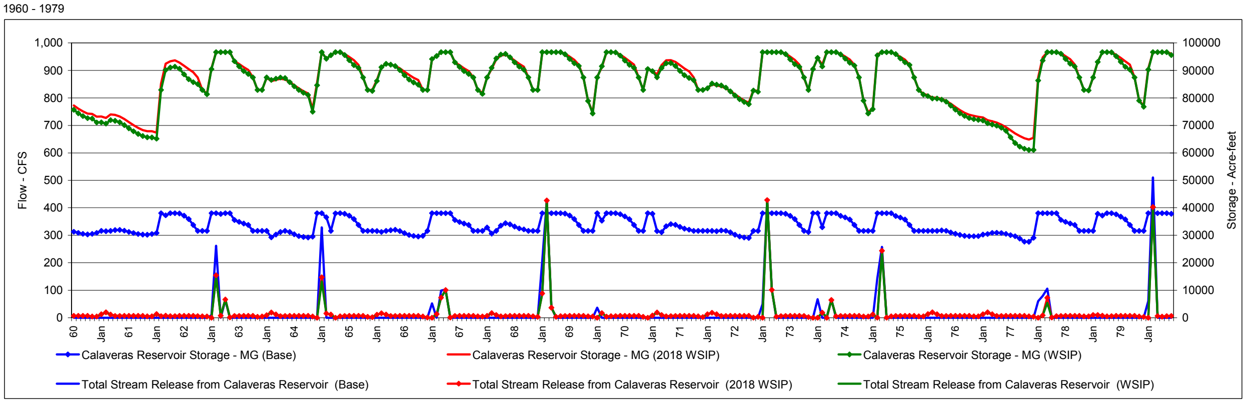
1920 - 1939



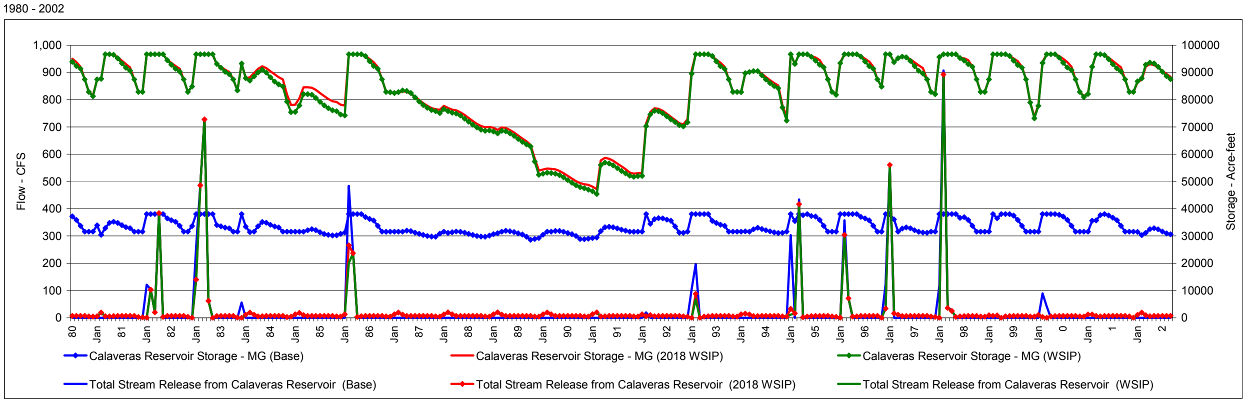
1940 - 1959



1960 - 1979

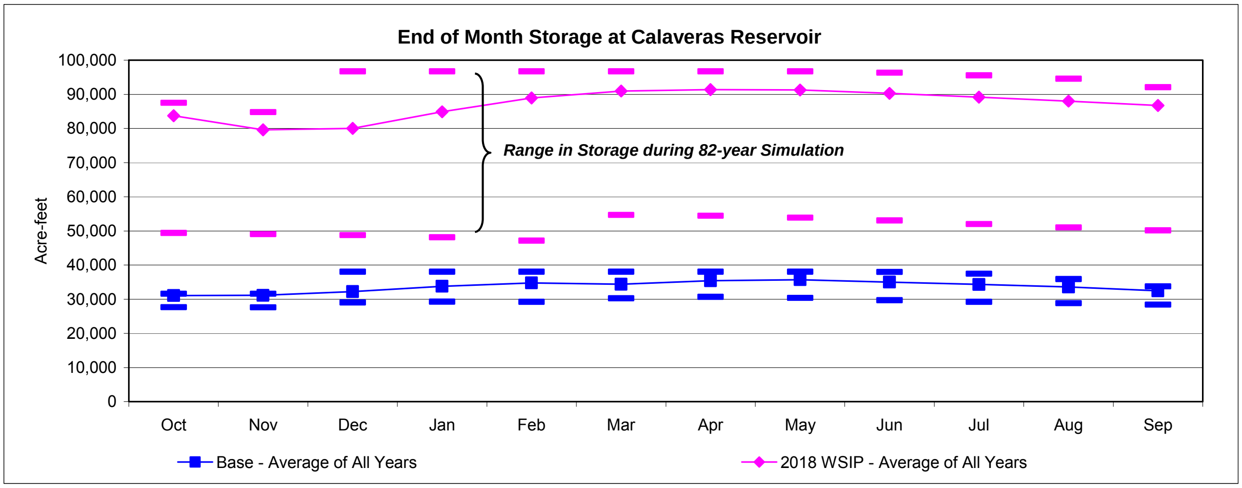


1980 - 2002



The difference in storage between the variant and WSIP settings and the base setting is due to the restoration of the operational capacity of Calaveras Reservoir. Under both the variant and WSIP settings the full capacity of Calaveras Reservoir would be available, and a greater range in storage operation would occur. Figure 2.6-2 illustrates the average monthly storage in Calaveras Reservoir for the 82-year simulation, and the range in storage for each month for the variant and base settings.

Figure 2.6-2



Compared to the WSIP setting, there would be the potential for either less or more release to Calaveras Creek below Calaveras Dam in the variant setting. Both settings require fishery releases below Calaveras Reservoir that are not included in the base setting. Calaveras Reservoir storage in the variant setting is sometimes more or sometimes less than in the WSIP setting; however, in either direction the difference is minor. Table 2.6-1 illustrates the difference in releases to Calaveras Creek between the variant and WSIP settings (considered insubstantial). Supplementing the Figure 2.6-1 representation of Calaveras Dam stream releases and Table 2.6-1 is Table 2.6-2, which illustrates the releases for the variant and WSIP settings, and the difference in releases between the two. Table 2.6-3 provides the same form of information for the variant and base settings. The notable difference in releases between the variant and base settings is the addition of the required flows to satisfy the 1997 CDFG MOU and the reduction of stream releases during wetter-year, wetter-season flows due to the restoration of Calaveras Reservoir operational capacity.

There would be very little, if any, difference in Alameda Creek diversions to Calaveras Reservoir in the variant setting compared to the WSIP setting. With essentially the same storage conditions between the two settings, there would be no difference in diversions from the Alameda Creek watershed. With no difference in diversions at Alameda Creek Diversion Dam (ACDD), flow spilling past the diversion dam would be the same in the variant setting. Table 2.6-4 illustrates the difference in flow below the ACDD between the variant and WSIP settings (considered insubstantial).

Table 2.6-5 illustrates the difference in flow below the ACDD between the variant and base settings. In this comparison, the reduction in flow below the diversion dam is due to the additional diversions to Calaveras Reservoir resulting from the restoration of reservoir operating capacity. Table 2.6-6 and Table 2.6-7 illustrate the flow past the ACDD, comparing the variant, WSIP, and base settings by year type and the average of all years.

Comparing the variant and WSIP settings, differences in releases from Calaveras Dam to the stream and differences to spills at the ACDD result in differences in flow below the Alameda Creek and Calaveras Creek confluence between the settings. Table 2.6-8 illustrates the flow below the confluence for the variant and WSIP settings. The modeled differences in these parameters were described above as insubstantial, and thus the combined effect of the differences at the confluence would also be insubstantial. Fishery releases for the 1997 MOU are assumed in both of the settings. Table 2.6-9 provides the same form of information for the variant and base settings. The notable differences between the variant and base settings (comparable to the differences between the WSIP and base settings) are the addition of required stream flows for the 1997 MOU and the reduction of wetter-year, wet-season flows due to the restoration of Calaveras Reservoir storage.

A flow recapture facility in Alameda Creek below Calaveras Reservoir is incorporated in the variant and WSIP settings. This facility is assumed to recapture flows explicitly released from Calaveras Dam for the 1997 MOU. The effect of the recapture would be a reduction in the flow below the confluence of Alameda and Calaveras Creeks, but only to the extent that releases were explicitly made from Calaveras Reservoir for the 1997 MOU. Flows below this diversion have been estimated and noted as the flow above the Alameda Creek and San Antonio Creek confluence. Table 2.6-10 illustrates the flow at this location for the variant and WSIP settings. The flow changes at this location are consistent with the changes noted for below the confluence of Alameda and Calaveras Creeks. These flow changes are considered insubstantial. Table 2.6-11 provides the same form of information for the variant and base settings. The flows identified at this location are indicative of flow occurring below the confluence of Alameda and Calaveras Creeks (described above) with the addition of estimated stream accretions between the Alameda and Calaveras Creek confluence and the Alameda and San Antonio Creek confluence, less the water assumed to be recaptured (diverted) by the SFPUC from the creek.

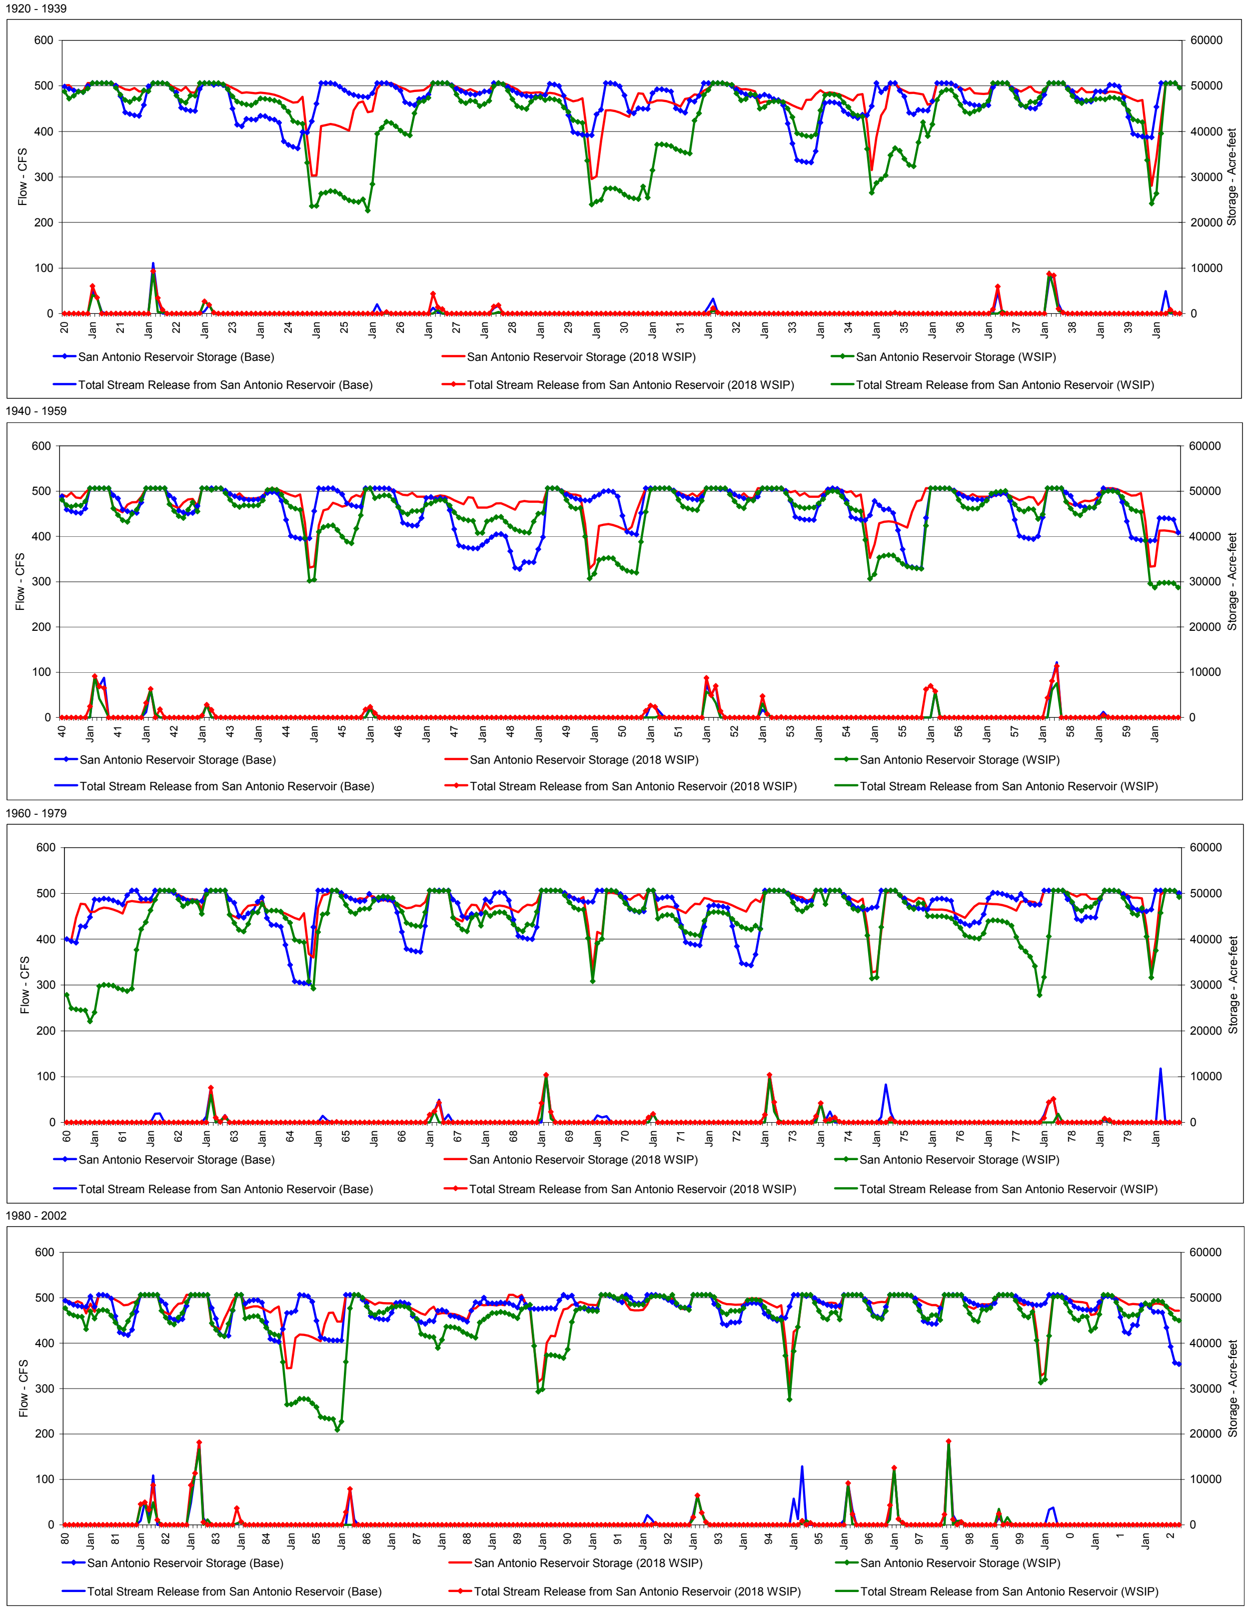
Compared to the WSIP setting, the variant's San Antonio Reservoir operation would typically draw less from storage on an annual basis, particularly during cyclic maintenance. Figure 2.6-3 illustrates a chronological trace of the simulation of San Antonio Reservoir storage and stream releases from San Antonio Dam. Shown in Figure 2.6-3 are the results for the WSIP, variant, and base settings. The difference in San Antonio Reservoir storage between the variant and WSIP settings is mostly caused by the lesser demand of the variant. Considering that Calaveras Reservoir storage is essentially the same between the settings, the difference in San Antonio Reservoir storage is indicative of the operational strategy to affect storage in San Antonio Reservoir more than storage in the other SFPUC Bay Area reservoirs. San Antonio Reservoir would retain more storage in the variant setting compared to the WSIP setting.

The difference in storage between the variant and WSIP settings and the base setting is due to the restoration of the operational capacity of Calaveras Reservoir. In the base setting, the limited operating storage capacity at Calaveras Reservoir leads to a different operation at San Antonio Reservoir, one that retains relatively more stored water for system demands when the draw from Calaveras Reservoir is constrained due to limited storage. There is also a notable difference in storage operation between the variant and WSIP settings and the base setting due to assumed maintenance. Assumed systematic maintenance of Hetch Hetchy conveyance facilities constrains diversions to the Bay Area from Hetch Hetchy every year, and particularly during every fifth year in the WSIP and variant settings.

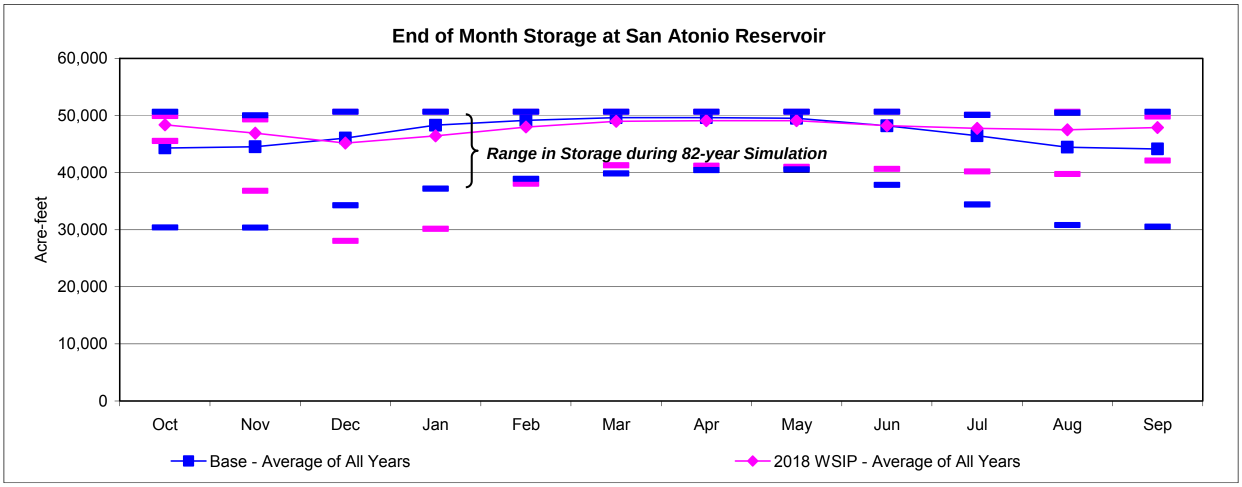
APPENDIX O3

Figure 2.6-3
San Antonio Reservoir Storage and Stream Release



The reduction in diversion from Hetch Hetchy during these periods is accommodated in the system by drawing additional water from the Bay Area reservoirs. The proportionate share of this operation that is directed toward San Antonio Reservoir is evident in the tracing of San Antonio Reservoir storage for the variant and WSIP settings. Figure 2.6-4 illustrates the average monthly storage in San Antonio Reservoir for the 82-year simulation, and the range in storage for each month for the variant and base settings. Compared to the base setting, the variant would draw less storage from San Antonio Reservoir, typically retaining a fuller reservoir except during the cyclic maintenance period November through January.

Figure 2.6-4



There is very little anticipated change in stream releases below San Antonio Reservoir between the variant and WSIP settings. Table 2.6-12 illustrates the modeled releases to San Antonio Creek from San Antonio Reservoir for the two settings and the differences for the average release during a year type. With a different reservoir operation at times during the winter, as seen in Figure 2.6-4, it is expected that there would be a difference in the ability to regulate reservoir inflow and avoid stream releases. Given the sometimes rigid constraints within the modeling assumptions, the model will overestimate the frequency and magnitude of stream releases from San Antonio Reservoir under any of the investigated settings. The flexibility that occurs in actual operations would likely avoid most of the releases represented by the model. The modeled stream releases from San Antonio Reservoir and the difference between releases for the variant and base setting are shown in Table 2.6-13. The differences between the two settings reflect a slight decrease in modeled releases. This modeled circumstance reflects the different resulting storage operation between the two settings, as seen in Figure 2.6-3. In most instances, the variant setting storage at San Antonio Reservoir during a period would be lower than that projected for the base setting during the same period. This circumstance could lead to an occasionally lesser modeled release for the variant setting, which is reflected in the results. As described above, the model will overestimate the frequency and magnitude of releases from San Antonio Reservoir, and the actual releases from the reservoir in any setting and the difference between settings are expected to be minor.

Flow below the confluence of Alameda and San Antonio Creeks is influenced by releases from San Antonio Creek and flow arriving at the location from Alameda Creek, which includes upstream impairment by SFPUC operations and facilities. Table 2.6-14 illustrates the flow below the confluence for the variant and WSIP settings, and the differences in flow between the two. The differences in flow between the variant and WSIP settings at this location are the net sum of the differences identified for flow reaching the location from Alameda Creek and from San Antonio Creek. The difference in flow from upstream in Alameda Creek was previously identified as insubstantial. Along with the conclusion that flow differences in San Antonio Creek would not be substantial, modeled differences below the confluence are also considered insubstantial.

Table 2.6-15 illustrates the same information for the variant and base settings. Table 2.6-15 shows the larger differences in flow that would occur between the variant and base settings. Those differences are particularly due to the effects of the restoration of Calaveras Reservoir operating capacity and the difference in San Antonio Reservoir storage operations.

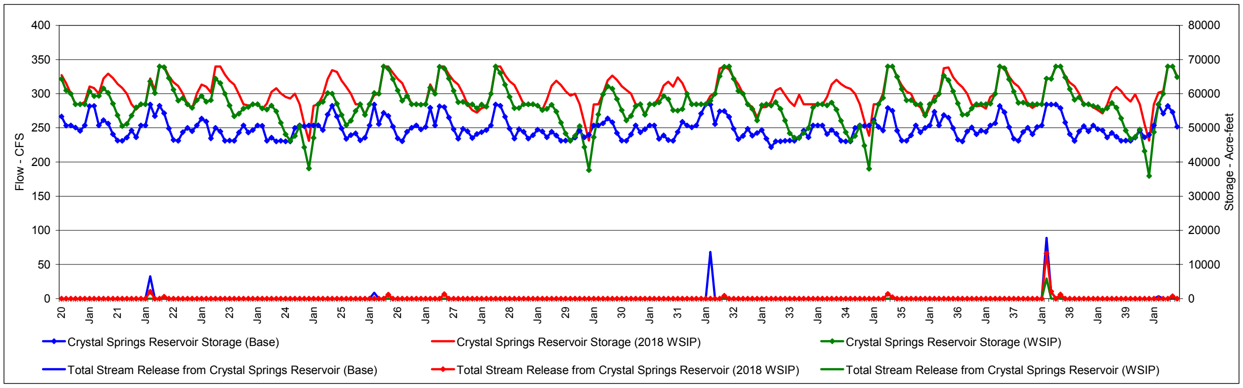
2.7 Crystal Springs and San Andreas Reservoirs

There are differences in Crystal Springs Reservoir operations among the WSIP, variant, and base settings. Figure 2.7-1 illustrates a chronological trace of the simulation of Crystal Springs Reservoir storage and stream releases from Crystal Springs Dam. Shown in Figure 2.7-1 are the results for the WSIP, variant, and base settings. Fundamental to the difference in storage operations between the WSIP and variant settings and the base setting is the restoration of reservoir operation capacity in the WSIP and variant setting that does not occur in the base setting. The result is the operation of Crystal Springs Reservoir at a lower maximum storage in the base setting. The difference in Crystal Springs Reservoir storage between the variant and WSIP settings is caused by the interaction of the increased demand served by the system's resources (a net 265 mgd for the variant and a net 290 mgd for the WSIP), which tends to lessen the operational range of the reservoir in the variant setting. Less drawdown and an accelerated replenishment of Crystal Springs Reservoir storage (as well as other Bay Area reservoirs) would occur with less systemwide demand to serve. The magnitude of the draw of storage from Crystal Springs Reservoir is partially dependent on the discretionary assumptions of the model that proportion the use of storage among the Bay Area system reservoirs. In actual operations, some of these differences may not occur, as system operators and prevailing hydraulic and hydrologic conditions may result in a different apportionment of effect among the reservoirs. However, the operational strategy prefers the retention of storage in the Peninsula reservoirs, similar to the strategy used by the model. Figure 2.7-2 illustrates the average monthly storage in Crystal Springs Reservoir for the 82-year simulation, and the range in storage for each month for the variant and WSIP settings.

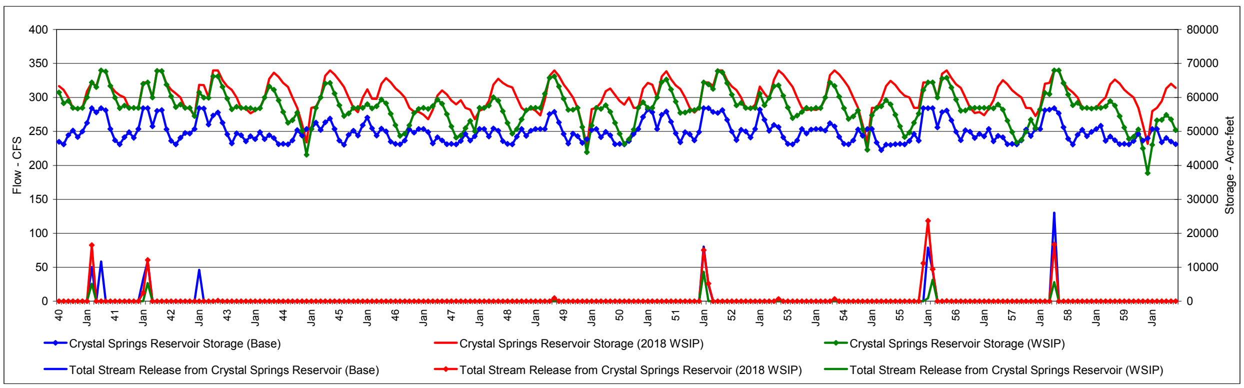
APPENDIX O3

Figure 2.7-1
Crystal Springs Reservoir Storage and Release

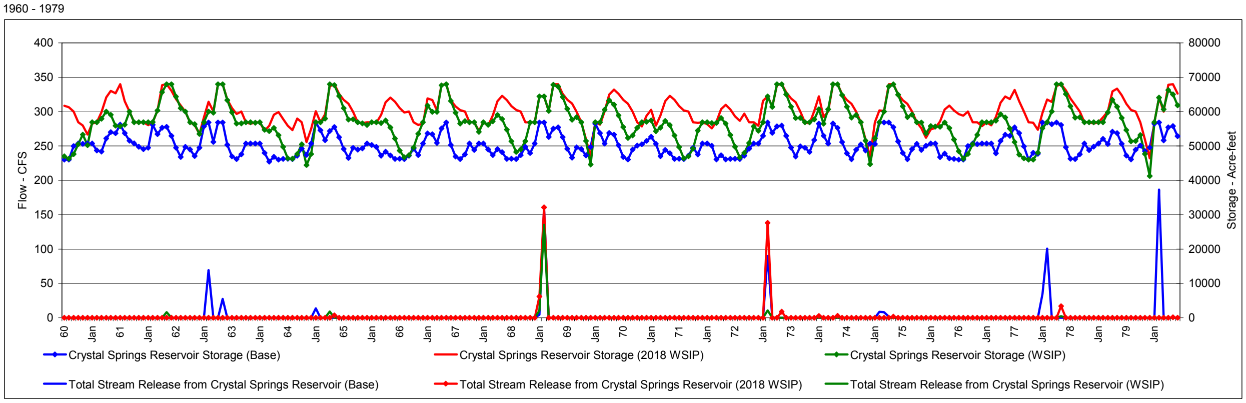
1920 - 1939



1940 - 1959



1960 - 1979



1980 - 2002

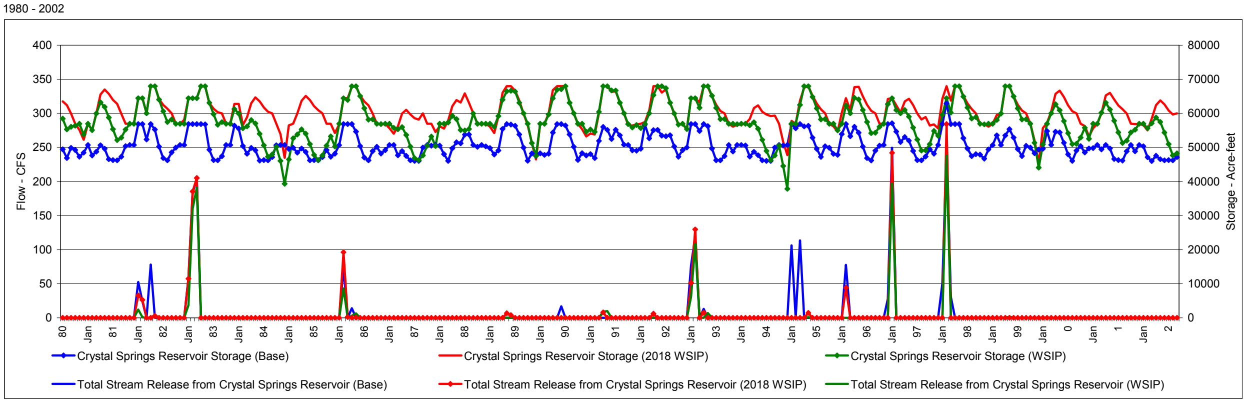


Figure 2.7-2

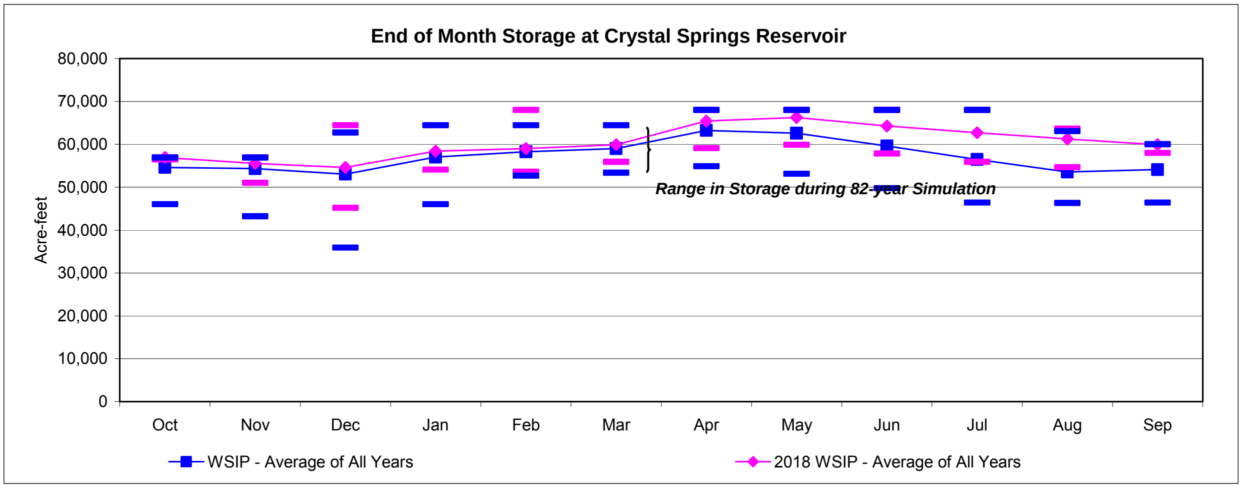

Figure 2.7-3 illustrates the average monthly storage in Crystal Springs Reservoir for the 82-year simulation, and the range in storage for each month for the variant and base settings. The variant setting would result in reservoir storage operating at a higher average level during all months, and the range of operating storage would be larger in some months.

Figure 2.7-3

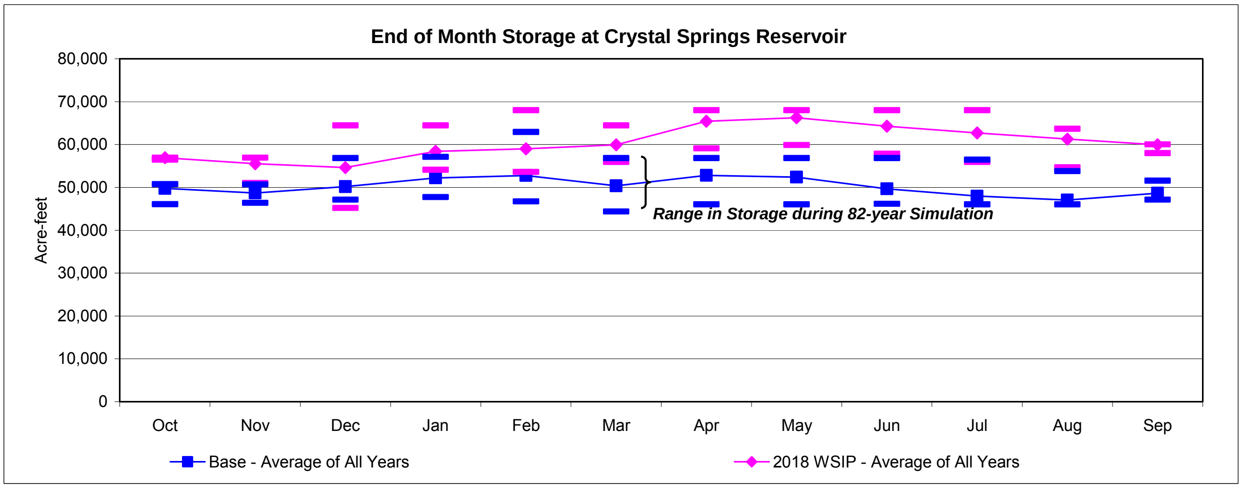

Table 2.7-1 illustrates the modeled variant and WSIP stream releases from Crystal Springs Reservoir and the differences between the two settings. Modeling results indicate that an increase or decrease in the occasional release could occur. The potential difference is attributed to a difference in the operating range of reservoir storage in the variant setting. In actual operations, it is anticipated that system operators would manage the reservoir system whereby stream releases would be minimal under any setting, and the effect would be essentially no difference between the variant and WSIP settings. Similarly, Table 2.7-2 illustrates the stream releases for the variant and base settings, and the difference in modeled flows between the two settings. A difference in Crystal Springs Reservoir storage between the two settings would lead to a different potential to regulate reservoir inflow, which could lead to different stream releases. However, as described above, actual system operations attempt to minimize releases under any setting, and thus the difference in releases between the variant and base setting is minimal, if any.

Reservoir storage at San Andreas Reservoir would follow a systematic filling and lowering each year; however, there would be slight differences in drawdown between the variant and WSIP settings, primarily due to the coincidence of the effects of different systemwide maintenance and water demands within each setting. Figure 2.7-4 illustrates a chronological trace of the simulation of San Andreas Reservoir storage and stream releases from San Andreas Dam. Shown in Figure 2.7-4 are the results for the WSIP, variant, and base settings. There are no projected stream releases from San Andreas Reservoir in any setting. Compared to the base setting, as Figure 2.7-4 illustrates, there would be a difference in storage operation every fifth year for the WSIP and variant settings. These differences would be the result of Hetch Hetchy conveyance maintenance, which is assumed to occur systematically in the variant and WSIP settings. The maintenance constrains the amount of Hetch Hetchy water supplied to serve water demands in the Bay Area. As previously discussed, during these winter periods the Bay Area reservoir system would accommodate the reduction in imported supply by serving the Bay Area water deliveries with the local watersheds' runoff and storage. At San Andreas Reservoir, serving this water demand would affect the reservoir when additional required water production at Harry Tracy WTP associated with WSIP or the variant exceeded the ability to maintain San Andreas Reservoir storage with pumping from Crystal Springs Reservoir. In the modeling, the conveyance capacity from Crystal Springs Reservoir is assumed to be the same among all of the settings. The additional water demand of the WSIP and variant require additional production from Harry Tracy WTP to be drawn from San Andreas Reservoir.

1980 - 2002

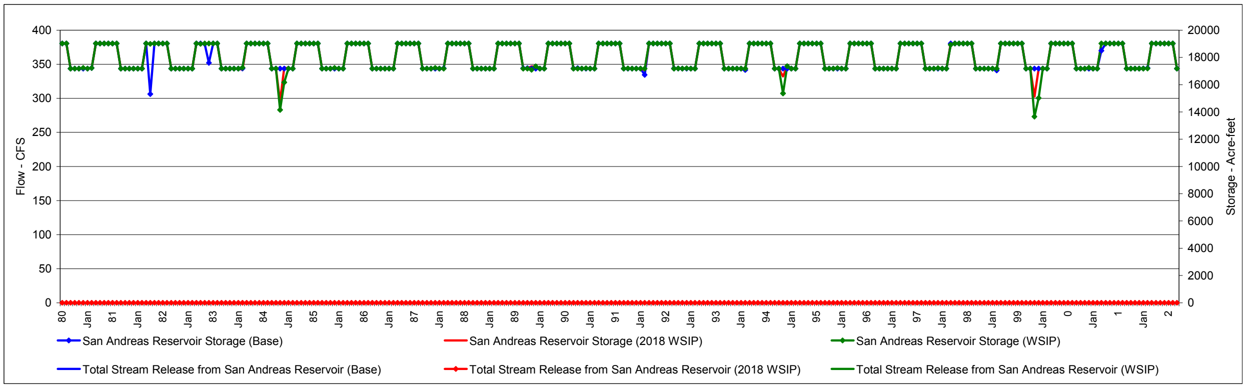

Figure 2.7-5 illustrates the average monthly storage in San Andreas Reservoir for the 82-year simulation, and the range in storage for each month for the variant and base settings.

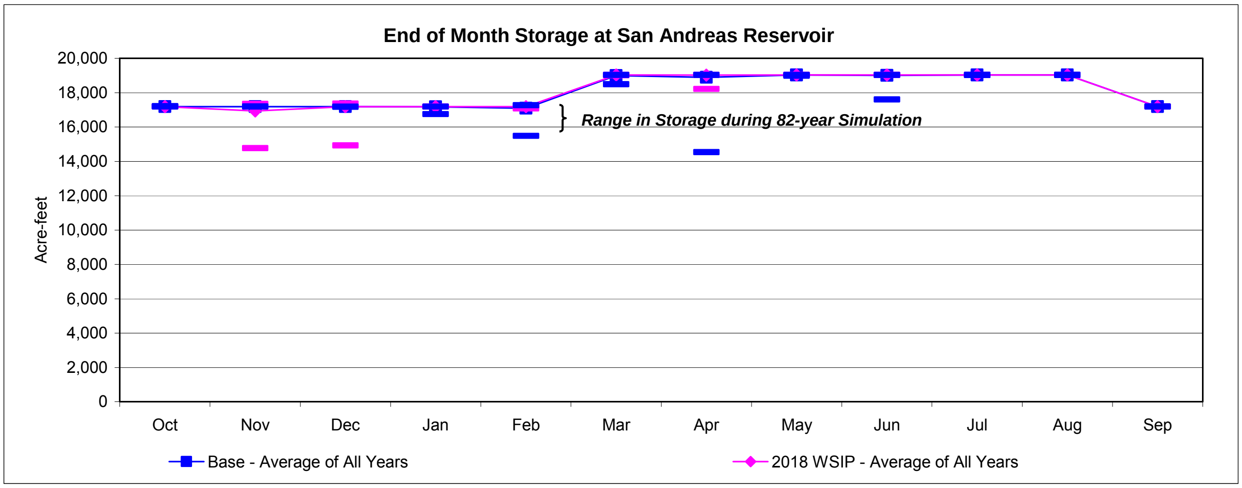
Figure 2.7-5



2.8 Pilarcitos Reservoir

Coastside County Water District's (Coastside CWD) water demand and its SFPUC purchase request are projected to increase within the WSIP planning horizon of year 2030. Within the context of the 2030 purchase request of 300 mgd, Coastside CWD's portion is estimated to amount to about 3 mgd. This projected purchase request is approximately 1 mgd greater that its current purchase request. Considering the current physical constraints on deliveries from the SFPUC to Coastside CWD and the ongoing planning activities in the watershed, the precise means of serving Coastside CWD's additional purchase request, and the resultant potential changes in the operation of SFPUC facilities and their affected environs, are uncertain.[2] For the variant, Coastside CWD's delivery would remain at its current level of approximately 1.8 mgd.

Assuming a range of potential means to serve the additional purchase request from Coastside CWD, the following are potential hydrologic effects on SFPUC facilities and their affected environs:

- Due to limited yield from Pilarcitos Reservoir, additional diversions would be required from Crystal Springs Reservoir.
- If deliveries to Coastside CWD from Pilarcitos Reservoir increase during the winter season, these deliveries could potentially reduce storage in Pilarcitos Reservoir, thereby potentially reducing diversions to the San Mateo Creek watershed. Although the increased delivery would increase releases to Pilarcitos Creek from Pilarcitos Dam for a period of time, the increase would subsequently lead to a reduction in spills past Stone Dam.
- Additional wintertime deliveries could also potentially impair the ability to provide carryover storage into the summer season from Pilarcitos Reservoir, and subsequently lead to an acceleration of the beginning of the season when releases to Pilarcitos Creek from Pilarcitos Reservoir consist only of the passage of reservoir inflow.
- An increase in summertime deliveries from Pilarcitos Creek could also accelerate the beginning of the season when releases to Pilarcitos Creek from Pilarcitos Reservoir consist only of the passage of reservoir inflow.

Figure 2.8-1 illustrates a chronological trace of the simulation of Pilarcitos Reservoir storage and stream releases from Pilarcitos Dam. Shown in Figure 2.8-1 are the results for the WSIP, variant, and base

[2] See *Analysis of SFPUC Pilarcitos/Coastside County Water District Operations*, Memorandum by Daniel B. Steiner, March 8, 2007.

settings. For the WSIP setting, the operation assumes an increase in purchase request by Coastside CWD, distributed on a proportionate monthly pattern during the year consistent with historical SFPUC deliveries. Also assumed is a conveyance constraint of 2 mgd to Coastside CWD from the Pilarcitos Creek source of water. When the assumed monthly purchase request of Coastside CWD exceeds this conveyance constraint, Coastside CWD's request is met with deliveries from Crystal Springs Reservoir. For the variant setting, Coastside CWD's demand is the same as depicted for the base setting.

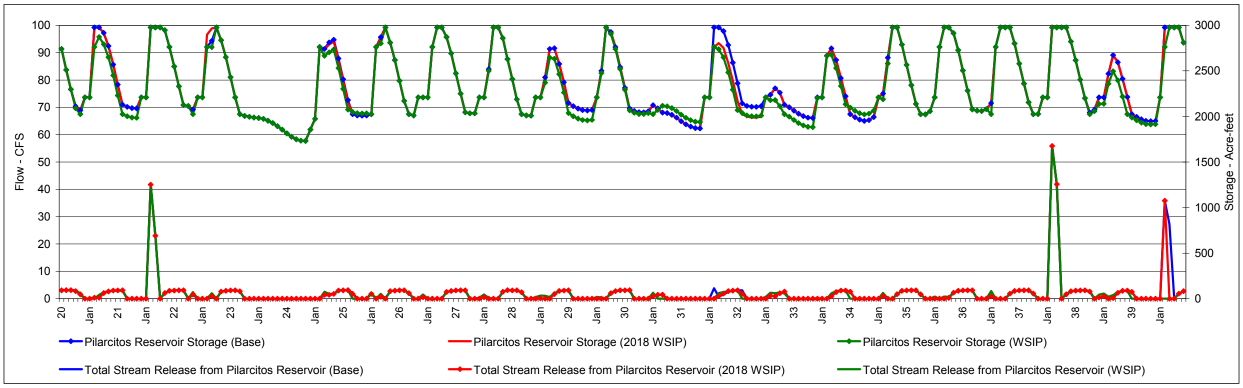
Compared to the WSIP setting, the variant would draw less water from Pilarcitos Reservoir, thus avoiding the effects on Pilarcitos Reservoir and its operations associated with the WSIP. A potential increased draw of storage from Pilarcitos Reservoir earlier in the year would not occur under the variant, and thus the earlier summertime reduction in Pilarcitos Reservoir releases to the Pilarcitos Creek would not occur. The variant's operation would be much the same as, if not identical to, that depicted for the base setting. Figure 2.8-2 illustrates the average monthly storage in Pilarcitos Reservoir for the 82-year simulation, and the range in storage for each month for the variant and base settings.

There are occasional differences in the operation of Pilarcitos Reservoir due to slight changes in the overall operation of the SFPUC system. These changes could affect the timing and frequency of the transfer of water from the Pilarcitos Creek watershed to the San Mateo Creek watershed.

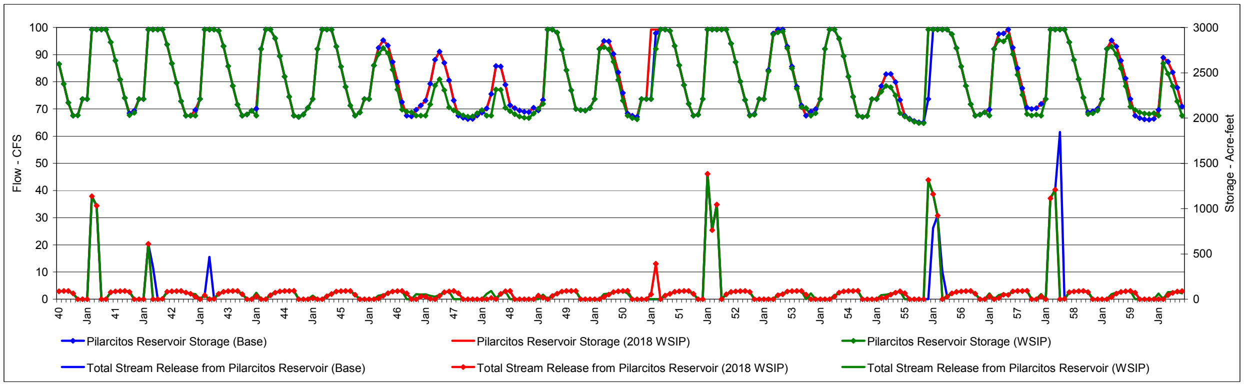
APPENDIX O3

Figure 2.8-1
Pilarcitos Reservoir Storage and Stream Release

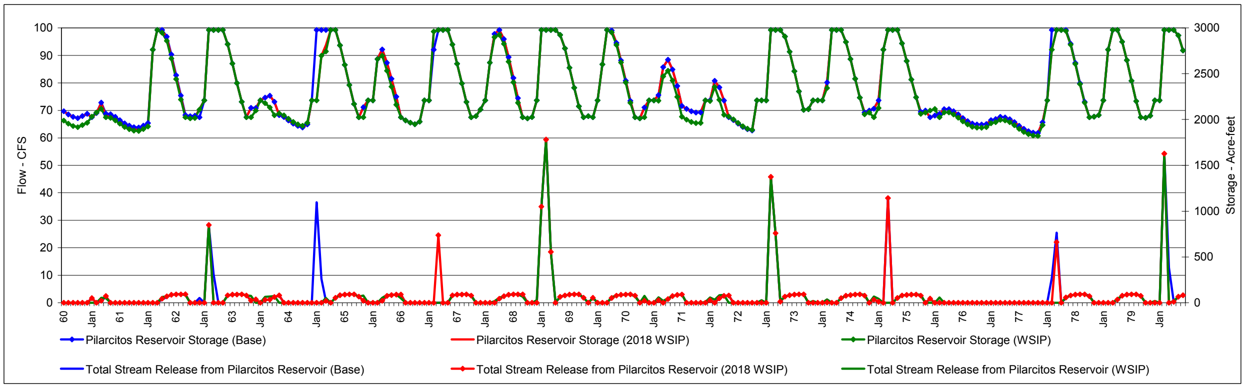
1920 - 1939



1940 - 1959



1960 - 1979



1980 - 2002

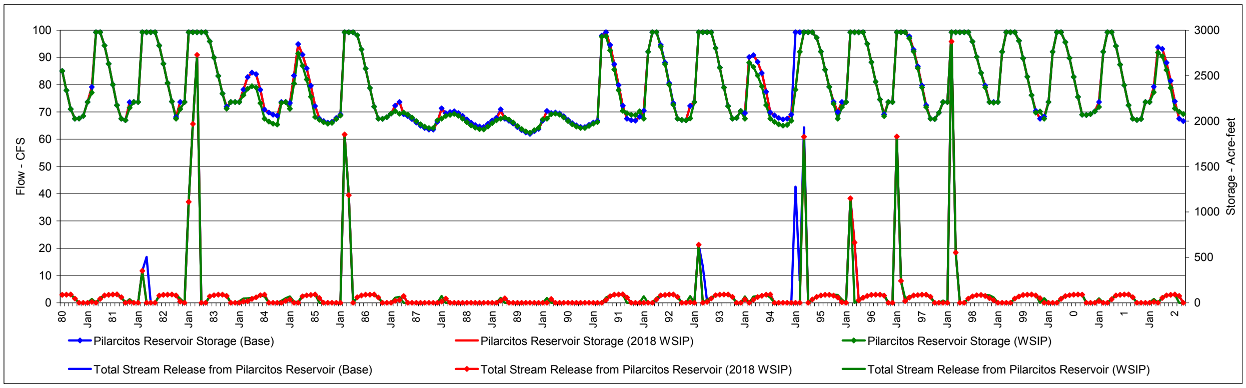


Figure 2.8-2

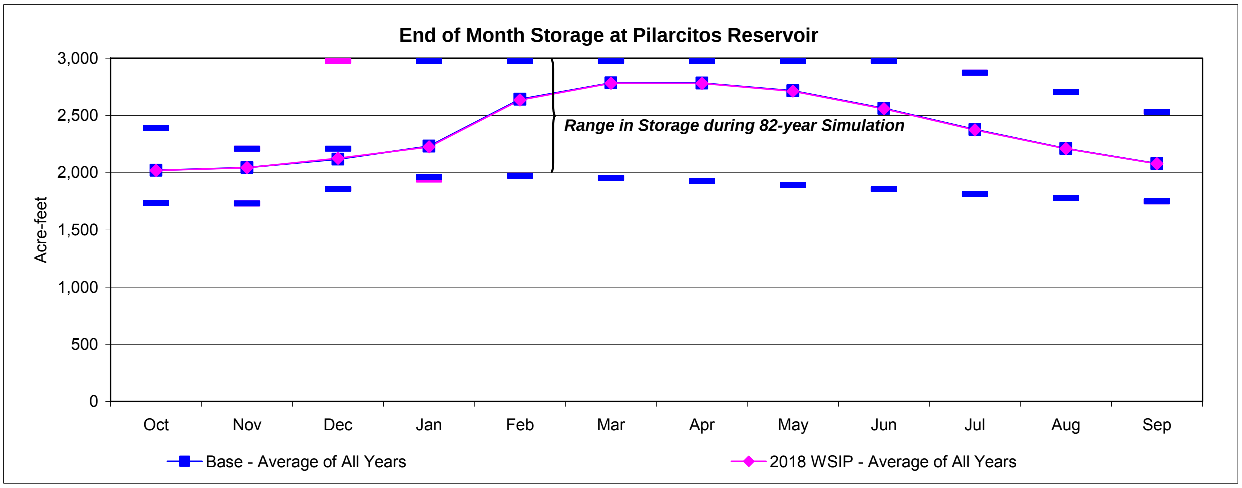

Stream releases from Pilarcitos Dam are also shown in Figure 2.8-1. Releases can occur for diversions at Stone Dam for Coastside CWD deliveries, conveyance to the San Mateo Creek watershed (e.g., Crystal Springs Reservoir), and reservoir spills. Pilarcitos Creek typically gains flow from unregulated tributary streams and runoff below Pilarcitos Dam. The differences in flow between the variant setting and base setting are shown chronologically in Table 2.8-1 and summarized by monthly averages within year types in Table 2.8-2. The reductions in flows during the winter and spring are indicative of the averaging of the few instances when additional water is transferred to the San Mateo watershed from Pilarcitos Reservoir.

The effect of the variant on Pilarcitos Creek flows below Stone Dam is different than the effect on flows below Pilarcitos Dam. Figure 2.8-3 illustrates the chronological trace of inflow to Stone Dam, which includes releases from Pilarcitos Dam to Pilarcitos Creek and unregulated flow to the stream below Pilarcitos Dam, and releases (spills) from Stone Dam to Pilarcitos Creek. Shown in the figure are the results for the WSIP, variant, and base settings. The flow past Stone Dam in all settings is typically minor (zero in modeling results, but may be measurable in terms of leakage and seepage past the dam), as inflow to the dam is diverted to Coastside CWD or to the San Mateo watershed. Releases past Stone Dam typically occur when unregulated flow below Pilarcitos Dam exceeds the delivery needs of Coastside CWD at a time when the storage level at Crystal Springs Reservoir rejects the water from the Pilarcitos watershed. There are a few instances when flow past Stone Dam in the variant setting would be diminished by the change in releases from Pilarcitos Reservoir. Table 2.8-3 summarizes the results for the variant and base settings in terms of average monthly flows by year type, and the average differences in flow between the two settings.

APPENDIX O4

Memorandum

Subject: **Analysis of WSIP upon the San Joaquin River and the Sacramento-San Joaquin Delta**
From: **Daniel B. Steiner**
Date: **May 22, 2008**

1. Introduction

This memorandum summarizes an evaluation of the potential effects of the WSIP on the hydrology and operations of the San Joaquin River and the Sacramento-San Joaquin Delta (Delta). The evaluation is based on a contrast of HH/LSM results for the simulation of the WSIP against the simulation of San Joaquin River and Delta hydrology and operations. The projected hydrology due to the WSIP is primarily discussed in terms of a comparison to the existing condition.

2. Setting

The Tuolumne River is one of the principal tributaries of the San Joaquin River. Combined with the operations of the Stanislaus River, the Merced River, and intermittent releases from the upper San Joaquin River, Kings River, and other lesser tributary and uncontrolled flow, the contemporary average annual flow in the Tuolumne River at Vernalis is estimated to be approximately 3,050,000 acre-feet per year (afy), with a very large variance between drought and flood conditions. Figure 2-1 illustrates the setting of the Tuolumne River within the San Joaquin River system.

The Tuolumne River experiences an average annual unimpaired runoff of approximately 1,850,000 afy, of which an average of approximately 669,000 afy are released at La Grange Dam to the lower Tuolumne River. Releases below La Grange Dam are guided by FERC flows requirements and range between 94,000 and 301,000 afy. Additional releases occur in excess of FERC requirements during wetter years. The general magnitude and distribution of current releases at La Grange Dam by year type are illustrated in Figure 2-2. The effect of the WSIP on the Don Pedro Project would be to reduce inflow to Don Pedro Reservoir, which, if not affecting TID/MID canal diversions, would lead to a depletion in Don Pedro Reservoir storage. The depletion in reservoir storage would be replenished during wetter years when, absent the WSIP, releases below La Grange Dam would be in excess of required FERC flows. The average annual reduction in flow below La Grange Dam due to the WSIP amounts to approximately 25,000 afy, primarily during wetter years and during the winter or spring period depending on the coincidence of the WSIP's effect on inflow and the sequence of month-to-month and year-to-year hydrology.

The hydrology of the San Joaquin River at Vernalis is illustrated in Figure 2-4. The hydrology at Vernalis is dependent on several factors, including incidental and prescribed operations within the basin for the San Joaquin River. Generally, the flow in the San Joaquin River is a result of the independent operation of the tributaries for purposes specific to their respective watershed basins. An amount of flow interaction with the river also occurs through groundwater accretions, diversions, and return flows from adjacent lands.

The U.S. Bureau of Reclamation's (USBR) Central Valley Project (CVP) New Melones Project regulates the Stanislaus River, which is operated for purposes of water supply, flood control, power generation, fishery enhancement, and water quality improvement in the lower San Joaquin River. The operations of the New Melones Project are partially guided by State Water Resources Control Board (SWRCB) decisions, including Decision 1422 pertaining to releases for existing water rights, fish and wildlife enhancement, and the maintenance of water quality in the Stanislaus River and San Joaquin River. Decision 1641 assigns additional responsibility to the USBR concerning flow requirements at Vernalis.

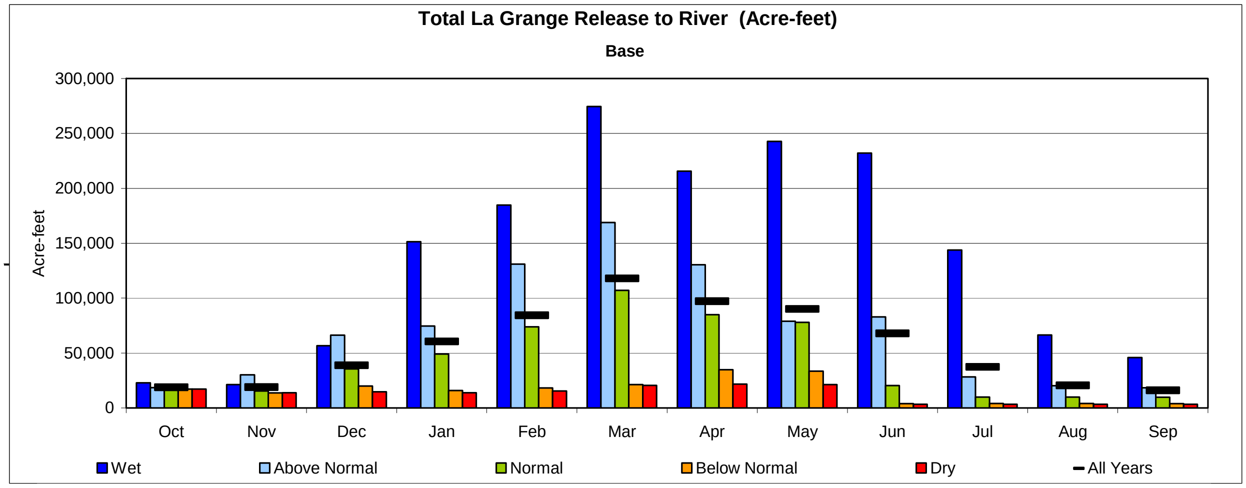

Figure 2-3
Tuolumne River Flow below La Grange Dam – WSIP Effect

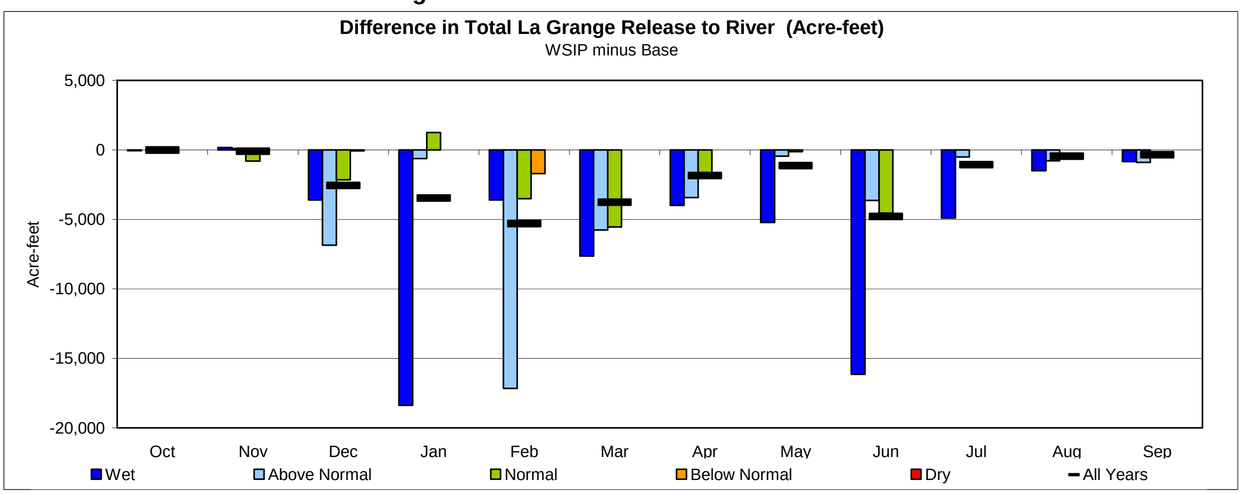

Figure 2-4
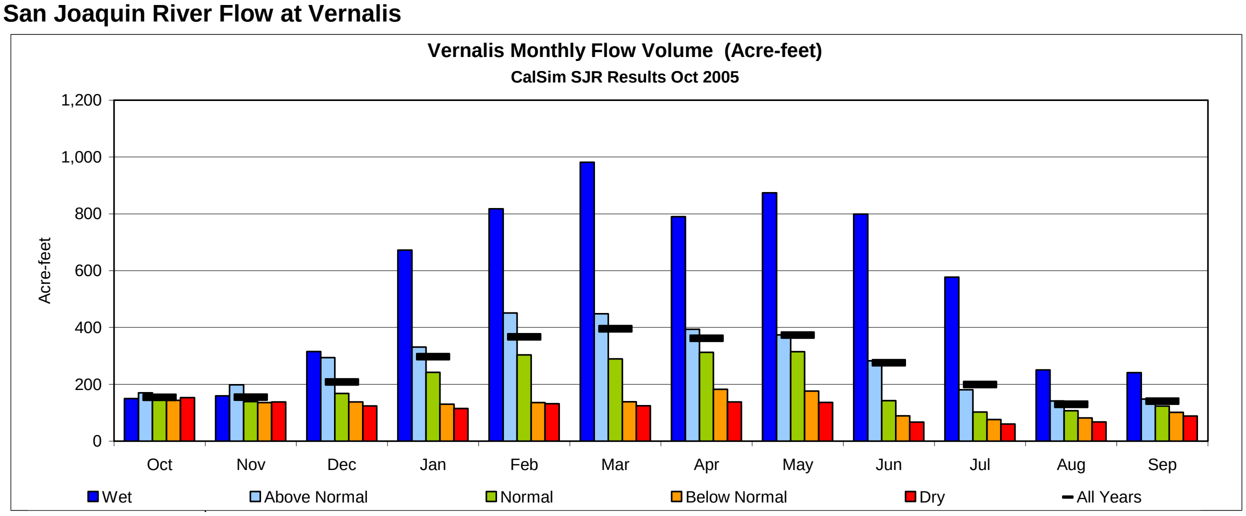
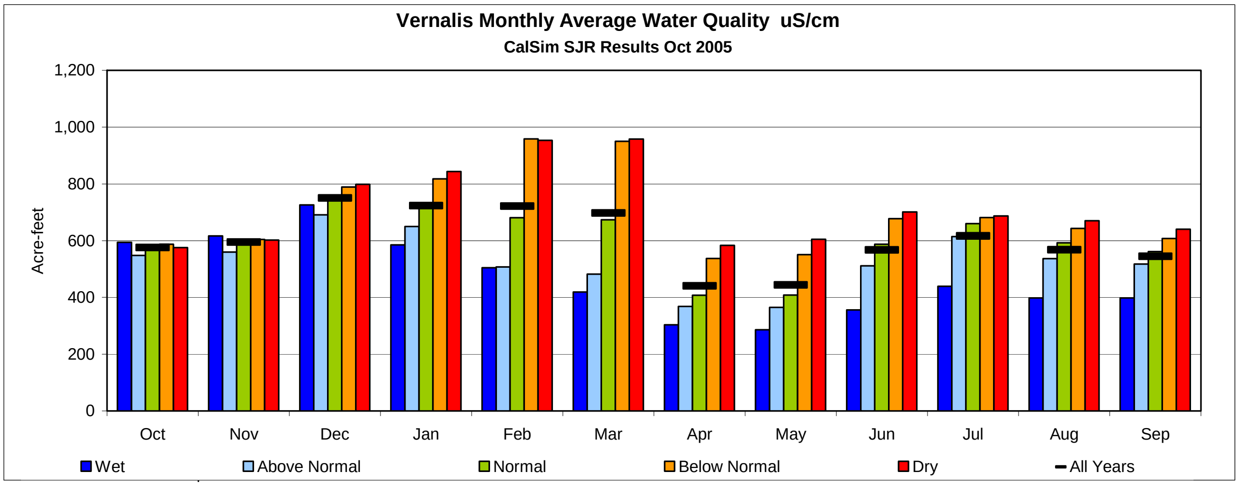
San Joaquin River Flow at Vernalis



APPENDIX O4

Water quality objectives at Vernalis are established as follows: for the irrigation season (April through August), a running 30-day average conductivity of 0.7 milliSiemens per centimeter (mS/cm); and during the rest of the year, 1.0 mS/cm. Flow requirements at Vernalis are established for the February through June period. Based on the wetness of the San Joaquin River Basin and the required location of a water quality parameter prescribed by Decision 1641 (called "X2"), the "base" required flow at Vernalis ranges between 710 cubic feet per second (cfs) and 3,420 cfs. During a 30-day period in April and May, the Vernalis Adaptive Management Plan (VAMP) flow objective ranges between 3,200 cfs and 7,000 cfs. The SWRCB has assigned the USBR the responsibility for compliance with the Vernalis flow standards, with other entities within the basin contributing towards compliance during the VAMP period through agreement. Water quality (electrical conductivity) at Vernalis is illustrated in Figure 2-5.

Figure 2-5
San Joaquin River Water Quality at Vernalis



The Delta forms the confluence of the Sacramento and San Joaquin Rivers, and is the eastern portion of the San Francisco Bay estuary. The CVP and the State Water Project (SWP) use the Delta channels to convey water to their respective export facilities in the southern Delta. Jones Pumping Plant (CVP) has a pumping capacity of 4,600 cfs; Banks Pumping Plant (SWP) has a pumping capacity of 10,300 cfs, although it is typically constrained to an average pumping capacity of 6,680 cfs. Figure 2-6 illustrates the geographical setting of the Delta.

Through coordinated operation, the CVP and SWP control releases from reservoirs and exports from the Delta to serve water supply contracts totaling several million acre-feet. The Coordinated Operating Agreement (COA) sets guidelines for sharing the supply as well as the responsibility for meeting water quality standards in the Delta. Currently, Delta water quality objectives are prescribed by the 1995 *Water Quality Control Plan for the San Francisco Bay/Sacramento-San Joaquin Delta Estuary* through SWRCB Decision 1641.

In addition to SWRCB requirements, the operations of the CVP and SWP are also affected by the objectives of their various authorizations, requirements under the Endangered Species Act, and legal directives. Most recently, in December 2007 a federal court constrained the export operations of the CVP and SWP while a new federal biological opinion is developed for delta smelt. Additional CVP and SWP operational constraints may be developed for the protection of salmon.

To provide a context for comparing changes in Tuolumne River flow, Table 2-1 illustrates several parameters of historical measured flow within the Delta. For the recent period 1995 through 2006, the average annual total exports from the Delta have amounted to approximately 5,585,000 acre-feet, as computed outflow has been 24,189,000 acre-feet. Measured San Joaquin River flow at Vernalis for the same period, which includes flow from the Tuolumne River, has been an average annual of 4,075,000 acre-feet.

Total Exports: Banks PP, Jones PP, Contra Costa Pumping

Sacramento River Inflow: Sacramento River and Yolo Byapss

San Joaquin R Inflow: San Joaquin River at Vernalis

Delta Outflow: Net computed outflow at Chipps Island

3. San Joaquin River

The effect of the WSIP on San Joaquin River hydrology is evaluated by a post-process analysis of operation simulations of the Tuolumne River system and the San Joaquin River Basin system. The Tuolumne River system, including the SFPUC regional water system and the Don Pedro Project, is modeled using the HH/LSM, as described in the PEIR. Results are provided from that model for the flow release to the lower Tuolumne River below La Grange Dam. Changes in those projected releases between the PEIR "base" study (current conditions without the WSIP) and a projected future condition (with the WSIP) provide the hydrologic data needed to track the WSIP's effects downstream of La Grange Dam. These projected changes in La Grange Dam releases to the Tuolumne River are combined with a separate San Joaquin River operation simulation to estimate the impacts of the WSIP on San Joaquin River hydrology and operations.

APPENDIX O4

CalSim II, a computer model developed jointly by the Department of Water Resources (DWR) and the USBR, is used to model the San Joaquin River Basin system and much of the Central Valley and Delta region water resources infrastructure system. Focused primarily on the operations of the CVP and SWP, CalSim II necessarily incorporates the simulated operations of non-CVP/SWP projects that exist on tributaries to the San Joaquin and Sacramento Rivers. Explicitly, the operation of the Don Pedro Project is modeled in CalSim II. Although the HH/LSM and CalSim II are different models, the underlying logic of Don Pedro Project operations for each of the models was developed coincidentally and produces very similar results.

A subset of the CalSim II model and its results are used for this analysis of San Joaquin River hydrology. Development of the CalSim II model during 2005 included a refinement of the depiction of San Joaquin River Basin operations and hydrology. For the development process, a stand-alone version of CalSim II focusing on San Joaquin River Basin operations was constructed. This version of the model uses a constant boundary condition for the geographical range of the system outside of the San Joaquin River Basin to speed up the processing of simulations. This approach to CalSim II modeling of the San Joaquin River Basin system is adequate for studies that focus on San Joaquin River operations, which are not greatly dependent on a broader CVP-SWP operation. The model's depiction of the San Joaquin River Basin's current operations and hydrology received a peer review (2005) and was described in a public workshop sponsored by the SWRCB during 2006. The CalSim II results used for that workshop are used for this analysis.[1]

3.1 Releases to the Tuolumne River at La Grange Dam

As described above, the effect of the WSIP on the Don Pedro Project would be to reduce inflow to Don Pedro Reservoir, which would lead to depletions in Don Pedro Reservoir storage. The depletion in reservoir storage would be replenished during wetter years when, absent the WSIP, releases below La Grange Dam would be in excess of FERC-required flows. Table 3.1-1 and Table 3.1-2 illustrate the projected monthly releases at La Grange Dam to the Tuolumne River for the WSIP and base settings for the 82-year simulation period (1921-2002). Table 3.1-3 illustrates the projected difference in releases at La Grange Dam due to the WSIP's effect on Don Pedro Project operations.[2] The average annual reduction in flow below La Grange Dam due to the WSIP would amount to approximately 25,000 afy, primarily during wetter years and during the winter or spring period depending on the coincidence of the WSIP's effect on inflow and the sequence of month-to-month and year-to-year hydrology. The projected difference in releases from La Grange Dam (comparing the WSIP and base settings), ranked in descending order of wetness in the San Joaquin River Basin runoff, is illustrated in Table 3.1-4. These changes in La Grange Dam releases to the lower Tuolumne River would change the flow in the Tuolumne River between La Grange Dam and the confluence with the San Joaquin River. The flow projected in the San Joaquin River between the Tuolumne River confluence and the Stanislaus River confluence would be similarly changed.

3.2 Flow Upstream of the Stanislaus River Confluence

The flow of the San Joaquin River upstream of the Stanislaus River confluence (commonly referred to as the "Maze" Boulevard crossing of the San Joaquin River) is a point of interest in the identification of San Joaquin River hydrology. The tributary operations upstream of the Stanislaus River confluence (e.g., the Tuolumne River and Merced River) are generally not required to be responsive to San Joaquin River conditions. Therefore, the changes in the hydrology of the San Joaquin River upstream of the Stanislaus River due to the WSIP can be described by the change in hydrology that occurs at La Grange Dam. Downstream of the Stanislaus River confluence, the San Joaquin River hydrology may also include the reactions of the USBR's New Melones Project (Stanislaus River) to changes in the river at Maze; that is, reactions to both flow and water quality conditions. Projected changes in San Joaquin River flow upstream of the Stanislaus River confluence at Maze are illustrated in Figure 3.2-1 through Figure 3.2-4.[2] The figures illustrate the wetness rank-ordered flow at Maze with the projected coincidental change in

[1] CalSim II studies supporting a presentation of the San Joaquin River Group Authority to the State Water Resources Control Board regarding CalSim II – San Joaquin River Basin Development, Refinements and Results, April 24, 2006. Notice and materials of workshop can be found at http://www.waterrights.ca.gov/baydelta/Notices.htm.

[2] La Grange Dam release results are from the HH/LSM. Maze and San Joaquin River results are from CalSim II.

APPENDIX O4

flow at La Grange Dam superimposed on that flow. The illustration depicts the current flow in the San Joaquin River and how the flow is projected to change due to the WSIP. Consistent with the discussion of flow changes at La Grange Dam, the figures for Maze flow illustrate that the projected flow changes at Maze would typically occur during wetter years, and that the more sizeable changes in flow would occur during years when the flows at Maze are relatively large.

3.3 Stanislaus River

The USBR operates the New Melones Project for several purposes, including flow and water quality conditions in the Stanislaus River and the San Joaquin River below the Stanislaus River confluence. Because the USBR has responsibility for San Joaquin River flow and water quality objectives, the agency will at times utilize New Melones Project releases to achieve compliance with those objectives. During these times, the USBR may provide flows from the Stanislaus River to supplement flows in the San Joaquin River. These supplemental flows may either provide for flow compliance at Vernalis or may provide dilution flow to comply with downstream water quality objectives. Changes in flow or water quality conditions upstream of the Stanislaus River such as would occur under the WSIP could at times cause a reaction of New Melones Project operations to maintain compliance with downstream water quality or flow objectives.

An analysis was conducted to identify the frequency at which the WSIP could affect the USBR's operation of the New Melones Project; the analysis consisted of superimposing the occurrence of flow changes at La Grange Dam upon the projected periods when releases from New Melones could be made explicitly for San Joaquin River flow or water quality compliance. Table 3.3-1 illustrates the results of the analysis. The numeric values shown in Table 3.3-1 represent the period and magnitude of the flow changes at La Grange Dam due to the WSIP. For instance, in June of 1922, there is a 16,000-acre-foot reduction in releases projected at La Grange Dam. In this instance, there is no release from the Stanislaus River explicitly for either water quality or flow conditions at Vernalis. Therefore, the change in releases at La Grange Dam would not lead to a change in Stanislaus River operations, and thus the change at La Grange Dam would track directly downstream in the San Joaquin River to Vernalis.

As illustrated in Table 3.3-1, only rarely (3 monthly instances within the 82-year analysis) would there be a potential conflict between WSIP-induced changes in releases and periods of controlled releases from the Stanislaus River for San Joaquin River flow or water quality conditions. The rarity of occurrence is expected, as the WSIP-induced effect would typically occur during wetter years when there are sufficient flows in the San Joaquin River and explicit releases from the Stanislaus River would not be required to achieve compliance with downstream water quality and flow objectives. The rare instances of potential conflict occurred during periods when flow objectives at Vernalis were a controlling condition of operations, and only once during a coincidental time of water quality control. If the flow in the San Joaquin River from the Tuolumne River was reduced during these periods of control, the USBR might increase its release from the Stanislaus River (or from other sources) to counter the reduction.

In those few instances, if the USBR released additional water to the Stanislaus River to offset the reduction in flow from the Tuolumne River, storage in New Melones Reservoir (maximum storage of over 2,400,000 acre-feet) could be reduced by the amount of the additional release. This reduction in storage could have an effect on a year's allocation of water to the several USBR uses of Stanislaus River water. These uses include deliveries to CVP New Melones Project water contractors and the instream fishery releases. The frequency and magnitude of such potential reductions was estimated through additional review of study results. In two of the three instances when a supplemental release by the USBR could occur (27,000 acre-feet in June 1927, and 12,000 acre-feet in February 1964), a reduction in New Melones Reservoir storage could carry into a year's allocation of deliveries to CVP contractors and fishery releases. For the 1927 example, CVP deliveries to the Stanislaus River contractors could be reduced by about 3,000 acre-feet in 1928 (out of a projected 46,000 acre-feet of delivery for that year). The allocated annual fishery releases could be reduced by about 12,000 acre-feet during a year like 1928, but that potential reduction would be incidentally countered with the 27,000 acre-feet increase in release due to the reaction to the decrease in flow from the Tuolumne River; thus, on an annual basis the Stanislaus River could experience greater flow in such a year. CVP Stanislaus River contractors currently receive an allocation of up to 90,000 afy, with sequential periods of no deliveries. The reduction in CVP deliveries during 1928 would represent about a 6 percent reduction in CVP supply during that year, a supply that is zero during a quarter of the time.

In the second instance, February 1964, a reduction in New Melones Reservoir storage could affect the current year's allocations of water supply. The estimated effect in that year to CVP Stanislaus River contractors would be zero, as no water supply was allocated to the contractors. Annual fishery releases would again be reduced for the year (about 6,000 acre-feet), but the river would incidentally have an increase in release of 12,000 acre-feet in February. A reduction to the CVP contractors' supply would not occur until a couple of years later, if at all, and within current allocation procedures would amount to about 1,000 acre-feet.

The third instance of potential effect on New Melones Project operations (June 1973) potentially occurs subsequent to the time that the current year's water supply allocations are made, thereby not affecting 1973 operations except for a reduction in New Melones Reservoir storage carried into 1974. Hydrology during 1974 is sufficiently wet that New Melones Reservoir is projected to spill during filling; thus, the additional release during 1973 would not affect water supply allocations in a subsequent year.

3.4 San Joaquin River at Vernalis

Current flow and water quality conditions at Vernalis are described in Section 2 above, and the potential changes in flow to the San Joaquin River due to WSIP-induced changes from the Tuolumne River are shown in Table 3.1-4. As described in Section 3.3 above, there would only be a rare instance when Stanislaus River operations would react to changes in the San Joaquin River due to the WSIP. Therefore, in almost all circumstances, the change in La Grange flows would track as a change in San Joaquin River flow at Vernalis (inflow to the Delta). While the absolute water quality at Vernalis would be slightly reduced with the reduction of Tuolumne River flow (which is of better quality), water quality objectives at Vernalis would continue to be met. Flow objectives at Vernalis would continue to be met if the USBR meets those objectives.

3.5 Sacramento-San Joaquin Delta

The CVP and SWP have the responsibility of providing compliance with the Delta water quality objectives prescribed by SWRCB Decision 1641. Additional operational constraints on the CVP and SWP are in place as a result of biological opinions and court decisions. The CVP and SWP would react to WSIP-induced changes to inflow to the Delta from the San Joaquin River. These reactions could manifest as changes in upstream releases or changes in exports from the southern Delta. A post-process analysis was used to identify the frequency and magnitude of the potential reaction of the CVP and SWP. Similar to the analysis described for the Stanislaus River and San Joaquin River evaluation, this analysis contrasts changes in La Grange Dam releases against Delta operational conditions.

Two different types of indicator analysis are used. The first is used to identify the coincidence of Tuolumne River flow changes and Delta "balanced conditions." A Delta balanced condition is the period of time when the CVP and SWP are explicitly balancing reservoir releases with export operations to provide a certain Delta outflow to meet either flow or water quality objectives in the Delta. A change in flow (e.g., from the San Joaquin River) would lead to the CVP and SWP modifying their reservoir releases or exports to react to the change in flow to the Delta. During periods when the Delta is in a balanced condition, a change in San Joaquin River flow could cause a change in CVP and SWP operations. During periods when the Delta is in an "excess condition," the change in flow would not necessitate a change in releases, but could cause a change in exports, as described later.

Table 3.5-1 contrasts Tuolumne River flow changes due to the WSIP against those periods when the Delta is projected to be in a balanced condition. The CalSim II study used for this analysis is derived from the report entitled *Draft State Water Project Delivery Reliability Report* (DWR, 2007).[3] The study represents a depiction of current CVP and SWP operations as affected by current regulatory requirements, including the emergency remedy measures specified by Judge Wanger to protect delta

smelt. The measures required by the court will be in place for an interim period, and a revised biological opinion and OCAP (Operations Criteria & Plan) could lead to different operational requirements. However, this study provides the best available depiction of current CVP and SWP operations in a format that is usable for this analysis. Also, while measures that are ultimately implemented by the CVP and SWP may differ from those measures assumed in this analysis, the conclusions of this analysis are not expected to significantly change.

Table 3.5-1 illustrates that the vast majority of instances of Tuolumne River flow change occur during Delta excess conditions. During these periods, it is unlikely that the CVP or SWP would modify their upstream reservoir operations in reaction to a change in inflow from the San Joaquin River. There are 26 months (out of the 82-year [984-month] simulation) during which a change in flow occurs during Delta balanced conditions. When there was a change, the change ranged from minimal (17 instances less than 10,000 acre-feet in a month) to three instances of change greater than 60,000 acre-feet in a month (June 1973: 60,000 acre-feet; June 1978: 89,000 acre-feet; and July 1993: 63,000 acre-feet). The average annual reduction in inflow during balanced conditions amounts to 7,000 acre-feet. When these reductions in inflow to the Delta occur, the CVP and SWP may elect to increase reservoir releases, decrease exports, or a combination of both. The larger instances of change occur during months when Don Pedro Reservoir is refilling during wetter years subsequent to prolonged drought.

A second analysis is used to identify the potential effect on CVP and SWP exports due to San Joaquin River flow changes. This second analysis is separate, but at times linked to the analysis previously described. During Delta balanced conditions, the CVP and SWP could choose whether to adjust releases or exports in reaction to a change in San Joaquin River flow into the Delta. However, current operational constraints can separately limit exports based on hydraulic conditions in the south Delta. Table 3.5-2 illustrates a bookend potential effect that WSIP-induced San Joaquin River flow changes could have on CVP and SWP exports. The analysis is focused on the January through June time period, which is the primary focus of the Judge Wanger emergency remedy measures to protect delta smelt. During this period, the allowable reverse flows in Old and Middle River are established. These flows are dependent on the hydraulics of the south Delta, including the amount of water that enters the Delta from the San Joaquin River. A general rule-of-thumb is that about 50 percent of the flow at Vernalis affects the flow in Old and Middle Rivers, and exports have almost a direct (1:1) effect on flow in Old and Middle Rivers. Thus, about one-half of the change in flow in the San Joaquin River will affect the amount of allowed export. Table 3.5-2 reports the amount of change in allowed export (in cfs) that would occur due to WSIP-induced reductions in flow in the San Joaquin River during the January through June period. The potential average annual effect on CVP and SWP exports amounts to approximately 10,000 afy. About half of the years of the analysis resulted in essentially no change in potential exports, and the remainder of the years showed a potential annual change ranging from 5,000 acre-feet to up to about 130,000 acre-feet. This analysis may overstate the reduction of exports due to WSIP-induced reductions in inflow to the Delta. The method of the analysis does not consider the shifting of export operations by the CVP and SWP to reduce the potential loss of exports. Nor does the analysis consider the potential occurrence of extremely high flow conditions in the San Joaquin River that would ameliorate the effect of a WSIP-induced flow reduction in the San Joaquin River.

As described above, the CVP and SWP operate their systems in an integrated and coordinated fashion, and, when a difference in hydrology occurs (such as a WSIP-induced flow change to the Delta), the CVP and SWP generally have two means to react: a change in releases and/or a change in exports. The two separate isolated analyses described above indicate the magnitude and frequency of changes in Delta inflow from the WSIP-induced effect on Don Pedro Project operations. The two separate potential CVP/SWP effects described above are not always additive, as the projects could select one export or release reaction over the other, or a combination of both.
